of a patient with cervical esophageal perforation are shown in Figure 42.2. Perforations of the upper third of the esophagus down to the level of the carina are treated by cervical drainage. This is easily performed through a left neck incision as depicted in Figure 42.3. Usually it is not necessary to find or close the perforation. However, ensuring complete drainage by opening the prevertebral fascia is of paramount importance. If the perforation is easily seen, it can be sutured with minimal difficulty. In all patients, we place a Penrose drain alongside the esophagus into the posterior mediastinum and bring it out through the inferior aspect of the neck incision. A gastrostomy or jejunostomy tube is placed for enteral feeding during the recovery period. Oral intake is prohibited for 1 week, and then the patient is restudied with contrast esophagography. If no extravasation is noted, the diet is advanced, the drain is removed, and the patient is discharged. If a leak persists, oral intake is again prohibited, enteral feeding is continued, and the patient is studied at 1-week intervals until resolution occurs. As long as there is no underlying distal esophageal pathology, essentially all adequately drained esophageal perforations will heal spontaneously.

Perforations of the middle third are best approached through a right fifth intercostal space thoracotomy. We favor a buttressed primary repair whenever possible, even in delayed presentations.²⁰ Material for buttressing the repair includes flaps of pleura, pericardium, diaphragm, omentum, or muscle. For small- to moderate-size repairs, we prefer an intercostal muscle flap. This is a reliable pedicled muscle flap based on the intercostal vessels. It should be harvested at the start of the procedure prior to the placement of retractors to avoid damage to the vascular pedicle. Once harvested, the chest is opened, all pleural collections are drained, and the perforation is localized. Necrotic tissue around the perforation is débrided. A vertical myotomy is performed to fully expose the rent in the

FIGURE 42.2. A: Barium swallow and (B) computed tomography scan showing cervical esophageal perforation. The patient was treated with drainage and 1 week of gastrostomy tube feeding. The follow-up swallow at 1 week showed resolution.

FIGURE 42.3. Approach for drainage of a cervical esophageal perforation.

A: Skin incision parallel to the anterior border of the left sternocleidomastoid muscle, extending from the level of the cricoid cartilage to the sternal notch. **B:** With the sternocleidomastoid muscle and carotid sheath retracted laterally and the trachea and thyroid gland medially, blunt dissection along the prevertebral fascia in the superior mediastinum is carried out. Injury to the recurrent laryngeal nerve in the tracheoesophageal groove must be avoided. **C:** Schematic drawing of the prevertebral space drained by this cervical approach. **D:** Two 1-in. rubber drains placed into the superior mediastinum are brought out through the neck wound to allow establishment of an esophagocutaneous fistula, which usually heals spontaneously. (Adapted with permission from Orringer MB. The mediastinum. In: Nora PH, ed. *Operative Surgery*, 3rd ed. Philadelphia: WB Saunders; 1990:370.)

FIGURE 42.4. Primary repair of esophageal perforation. The edematous mucosa pouting through the muscular defect (*inset*) is grasped with Allis clamps and elevated. A 1-cm vertical esophagomyotomy is made at either end of the muscular defect to expose the entire limits of the tear. This is facilitated by using a right-angle clamp to direct muscularis away from underlying submucosa around the entire circumference of the tear. The result of this mobilization is exposure of a circumferential rim of normal submucosa that can then be closed. (Adapted with permission from Whyte RI, Iannettoni MD, Orringer MB. Intrathoracic esophageal perforation: the merit of primary repair. *J Thorac Cardiovasc Surg* 1995;109:140.)

mucosa, which almost always extends beyond the tear in the muscularis. The proximal and distal extent of the mucosal tear must be fully visualized and repaired; failure to do so will result in persistent leakage. We repair the mucosa with interrupted absorbable sutures and then reapproximate the muscular layer with interrupted fine silk suture. The intercostal muscle is then secured as an onlay patch. The steps involved in the operation are depicted in Figure 42.4. Large chest tubes are placed, and the patient is recovered. Enteral access either via a gastrostomy tube or jejunostomy tube aides in postoperative nutrition. A contrast swallow is performed on postoperative day 7. If there is no ongoing leakage, an oral diet is restarted and the chest tubes are removed. Persistent leaks are treated conservatively with chest tube drainage and alternative nutrition as long as the leak is well drained and there is no sign of clinical instability. If such a patient becomes systemically ill, CT scanning is indicated to identify any undrained collections. Reoperation with the goal of obtaining better and more complete drainage may be required on occasion. Depending on the findings of the CT scan and reexploration, the leaking repair may need to be taken down and the esophagus excluded with a cervical esophagostomy. If this is required, subsequent reconstruction can be very challenging; therefore, exclusion with diversion is reserved for those patients in whom there is no other viable alternative.

Perforations of the distal third of the esophagus, such as the classic Boerhaave rupture, are approached via a left seventh intercostal space thoracotomy. Again a pedicled intercostal muscle flap is harvested, the chest is opened, the mediastinum is drained, and the perforation site is identified, most commonly in the left posterolateral wall of the esophagus 2 to 3 cm proximal to the esophagogastric junction. The technique for primary repair and postoperative management is the same as described previously.

The operative treatment of esophageal perforation in patients with underlying esophageal pathology deserves special consideration. Repair of a proximal perforation with distal obstruction will fail, and the obstructing lesion must be

addressed at the initial procedure. For distal strictures, simple intraoperative dilation will usually decompress the esophagus to allow healing of a proximal perforation.

Patients with achalasia who are perforated during pneumatic dilation warrant separate discussion. Most have small, asymptomatic mucosal tears or well-contained small perforations and as such are candidates for nonoperative management as long as the dilation has successfully relieved the distal obstruction. For those who fail nonoperative management or do not qualify for it, the decision on how to proceed surgically requires thought and discussion. In patients with achalasia and preserved esophageal motility, the perforation should be repaired primarily, a vertical esophageal myotomy should be performed 180 degrees opposite the injury, and a noncircumferential wrap such as a modified Belsey fundoplication should be performed. Recently it has been demonstrated that a “floppy” or loose Nissen fundoplication or 360-degree wrap may be just as acceptable and likely to be more familiar to the surgeon who does esophageal surgery only on an occasional basis. For patients with decompensated achalasia, a sigmoid nonfunctional esophagus, and a perforation who are hemodynamically stable, consideration should be given to performance of esophagectomy with immediate restoration of gastrointestinal continuity.

Unstable patients with thoracic esophageal perforation and associated severe underlying esophageal pathology should be treated with exclusion and diversion. This includes an end cervical esophagostomy, pleural drainage, stapled division of the gastroesophageal (GE) junction, and placement of gastrostomy and jejunostomy tubes. If the patient survives, he or she can be brought back to the operating room at a later time for restoration of gastrointestinal continuity, usually following 6 to 8 weeks of recovery.

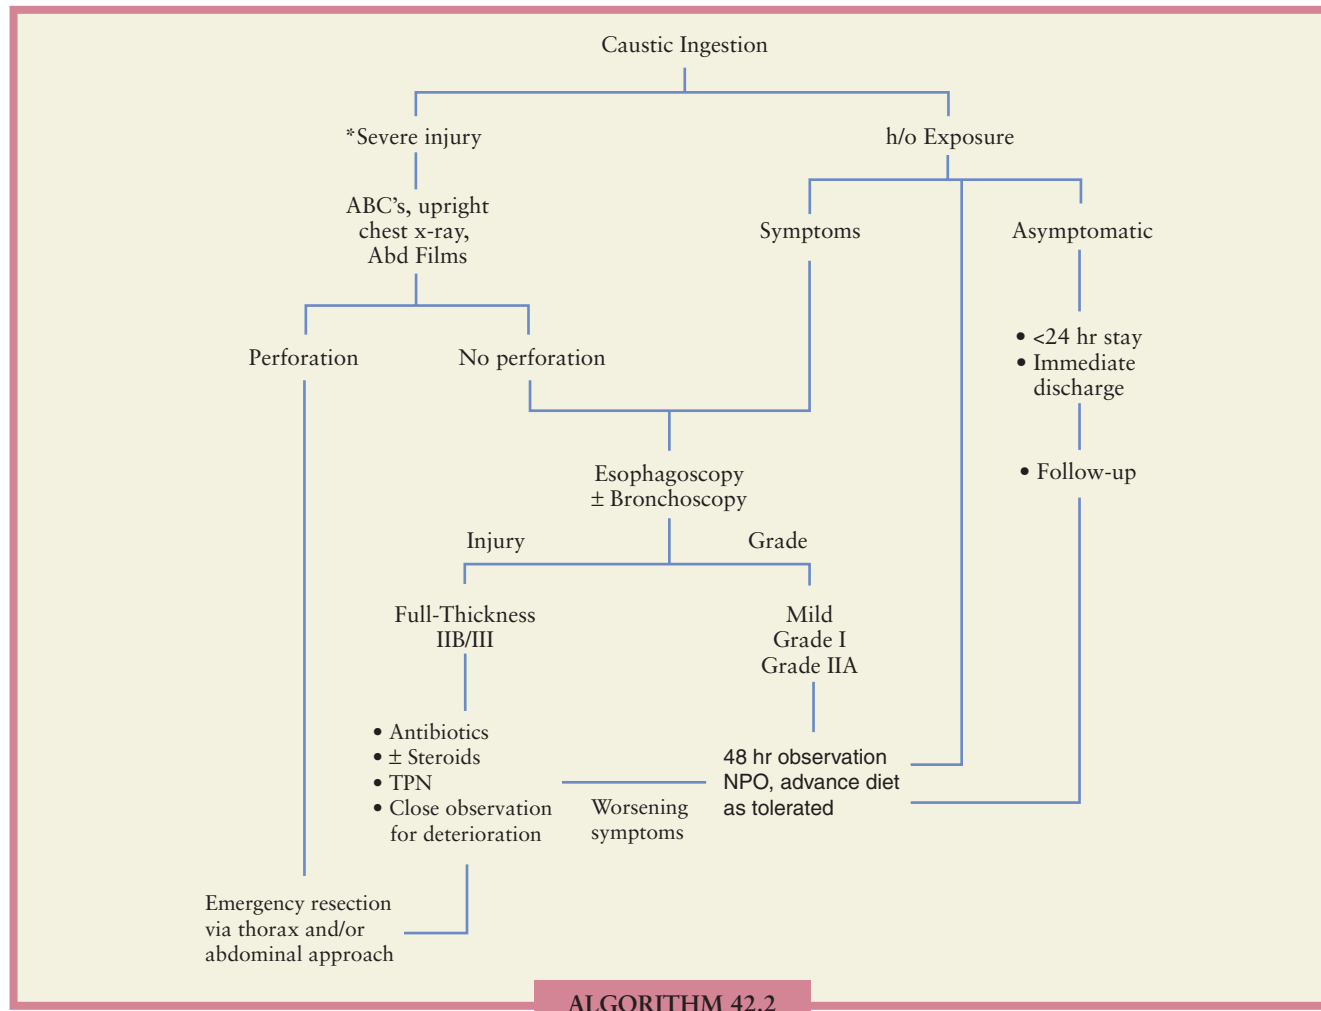

Foreign Body

Foreign body ingestion typically occurs in pediatric, psychiatric, alcoholic, and elderly patients. Most objects remain in the cervical esophagus; blunt objects as well as small sharp objects usually can be removed either by flexible and/or rigid esophagoscopy. Objects such as fish and chicken bones can be reoriented with a long grasper and easily brought out through a rigid esophagoscope. Large, rigid foreign bodies with sharp edges embedded in the mucosa and those that exceed the diameter of the rigid endoscope in all orientations pose a particularly difficult problem and may require esophagotomy for removal. Following endoscopic removal of a foreign body, completion esophagoscopy and contrast esophagography should be performed to rule out esophageal perforation. If a perforation is present, the patient is managed according to the esophageal protocol presented in Algorithm 42.1.

Caustic Injury

Caustic injury to the esophagus occurs following ingestion of either strong acids or strong base chemicals, usually household cleaning products. Ingestions in children are usually accidental and the quantities involved small. Ingestions in adults are often associated with a suicide attempt or psychiatric illness. The quantities swallowed in this group can be quite large and the injury extensive. Fortunately, these types of ingestion injuries are relatively rare today when compared to the number formerly seen.

Management of caustic ingestion injuries requires experienced surgical judgment.²¹ The first step in caring for any patient following caustic ingestion is airway protection. Burns to the oropharynx result in ongoing edema and may cause loss of the airway. A tracheostomy should be performed early if this is suspected. The second step is to determine the type of agent, the approximate quantity, and the time since ingestion.

ALGORITHM 42.2

ALGORITHM 42.2. Evaluation and management of acute caustic ingestion. (Adapted with permission from Paidas CN. Caustic burns of the esophagus. In: Yang SC, Cameron DE, eds. *Current Therapy in Thoracic and Cardiovascular Surgery*. St. Louis: Mosby; 2004:99.)

Unfortunately, history and physical examination alone are not predictive of the degree of esophageal injury. Severe injury can occur in the absence of significant oropharyngeal burns; thus, examination of the esophagus is required. When the ingestion is minor or questionable and there are no symptoms, the patient should be observed and flexible upper endoscopy is carried out at 24 to 48 hours. This timing allows for an adequate endoscopic evaluation of the injury, whereas immediate endoscopy may underestimate the extent of esophageal damage.

In symptomatic patients or those with suspected large ingestions of strong caustic agents, immediate esophagoscopy should be performed. The esophageal injury is graded endoscopically as shown in Table 42.2. This information is used to determine the appropriate treatment. The acute management is summarized in Algorithm 42.2.

TABLE 42.2 CLASSIFICATION

ENDOSCOPIC GRADING OF ACUTE CAUSTIC INJURY TO THE ESOPHAGUS

INJURY GRADE	ENDOSCOPIC APPEARANCE	DEPTH OF INJURY
I	Superficial hyperemia	Mucosal
II A	Sloughing mucosa, superficial ulceration	Patch partial thickness
II B	Deep ulceration	Circumferential
III	Eschar, necrosis	Full thickness

BENIGN NEOPLASMS

Table 42.3 shows a complete listing of the benign neoplasms of the esophagus. All are rare. Leiomyoma is the most common benign esophageal neoplasm and is subsequently discussed in detail. Esophageal polyps are also seen with some frequency at referral centers and deserve mention. Other benign neoplasms occur so infrequently that they are not individually discussed in this chapter.

Leiomyoma

Leiomyomas account for roughly two thirds of all benign tumors of the esophagus.²² The incidence of leiomyoma reported in autopsy series ranges from 0.005% to 5.1%.²³ Approximately 80% of leiomyoma are located intramurally and originate in the muscularis propria. Roughly 90% are

located in the middle and lower esophagus, reflecting the relative paucity of smooth muscle in the upper esophagus. They are slow-growing tumors, and therefore the size of the lesion may not change for many years. Leiomyomas usually present as single lesions, although cases of multiple lesions have been reported.²⁴ Figure 42.5 shows the typical esophagogram of a midthoracic esophageal leiomyoma; note the smooth-walled appearance of the lesion, indicating that the mucosa is not involved by this submucosal lesion. Figure 42.6 shows the endoscopic appearance of a distal esophageal leiomyoma.

Evaluation of a patient with a suspected leiomyoma usually includes a barium swallow, endoscopy, endoscopic ultrasound (EUS), and a CT scan of the chest. The utility of EUS lies in its ability to ascertain the layer of origin of a submucosal mass. In cases where the diagnosis of leiomyoma is in question, EUS-guided fine-needle aspiration (EUS-FNA) may be used to obtain tissue for histologic study including immunohistochemical (IHC) analysis. IHC in particular can differentiate leiomyoma from more aggressive entities such as gastrointestinal stromal tumor (GIST) and leiomyosarcoma and therefore assist in surgical planning.²⁵ However, FNA should not be routinely performed in the evaluation of suspected leiomyoma, as preoperative biopsy has been shown to increase the risk of mucosal perforation at the time of surgical enucleation.²⁶

FIGURE 42.5. Esophagogram of a leiomyoma. The acute angle at its junction with the esophageal wall is typical. (Reproduced with permission from Orringer MB. Tumors of the esophagus. In: Sabiston DC Jr, ed. *Textbook of Surgery*, 13th ed. Philadelphia: WB Saunders; 1986:736.)

Indications for resection of an esophageal leiomyoma include symptoms of dysphagia, increase in tumor size, mucosal ulceration, and to definitively establish a diagnosis to rule out a malignant process such as a leiomyosarcoma. The surgical approach to these lesions depends on the size, location, and character of the leiomyoma. Leiomyomas of the midesophagus are approached via the right thorax, whereas those in the distal esophagus or esophagogastric junction are best approached via the left chest or abdomen. Leiomyomas less than 8 cm without annular characteristics are best treated by surgical extramucosal enucleation and subsequent closure of the myotomy. Results of enucleation via thoracotomy are excellent, with mortality less than 1% and greater than 90% of patients symptom-free at 5 years.²⁷ Minimally invasive approaches to enucleation have become increasingly common in recent years, particularly for tumors smaller than 5 cm. Right thoracoscopy is used for middle esophageal tumors and laparoscopy for those of the distal esophagus or EG junction.²⁸ Leiomyomas greater than 8 cm or annular in character usually require esophageal resection. Treatment of the asymptomatic patient with a small leiomyoma (<3 cm) is controversial and can include either nonoperative surveillance or resection.²⁷ The process we use for evaluation and treatment of esophageal leiomyoma is shown in Algorithm 42.3.

Fibrolipomas and Fibrovascular Polyps

Esophageal fibrolipomas present as intraluminal cervical esophageal polyps. The peristaltic action of the esophagus may cause this lesion to elongate over time and reach extraordinary lengths.²⁹ Patients present with dysphagia. The lesion almost

always originates in the cervical esophagus; it is usually on a stalk and can be removed endoscopically. Very large lesions may require cervical esophagotomy or occasionally right thoracotomy for removal. Rarely, these polyps can present protruding from the mouth after an episode of coughing or emesis (Fig. 42.7). With large polyps, asphyxiation has been reported when the stalked polyp “flips” into the airway and becomes trapped. They should be excised.

FIGURE 42.7. This patient presented with a large esophageal polyp protruding from her mouth following an episode of coughing. This polyp was found to originate from a narrow stalk in her cervical esophagus and was removed endoscopically. Of note, she had undergone operative resection of a cervical esophageal polyp earlier in life.

MALIGNANT NEOPLASMS

Malignant neoplasms of the esophagus include adenocarcinoma, squamous cell carcinoma, small cell carcinoma, leiomyosarcoma, rhabdomyosarcoma, fibrosarcoma, liposarcoma, lymphomas, and metastatic lesions from distant primary sites. Adenocarcinoma and squamous cell carcinoma are the most frequent malignant lesions, and adenocarcinoma has emerged in recent years as the more common lesion (Fig. 42.8).

6 In fact, the incidence of esophageal adenocarcinoma has increased in the last 25 years greater than the incidence of any other major malignancy in the United States (Fig. 42.9).³⁰ Most thoracic surgeons will complete an entire career without seeing the less common types of esophageal malignancies.

7 The goal of esophageal resection, whether as primary treatment or as part of a multimodality plan, is cure, though this goal remains elusive. Palliative esophagectomy is associated with mortality rates in excess of 20% and morbidity rates as high as 50% and should therefore be avoided.³¹ Very effective palliation can be obtained with chemotherapy, radiation therapy, and endoscopic interventions such as stenting. Surveillance, epidemiology and end results (SEER) data from the National Cancer Institute estimate that 16,470 Americans will be diagnosed with and 14,280 will die of esophageal cancer annually. The lifetime risk of developing esophageal cancer is about 0.5%, being slightly higher for men than women.

Tobacco, alcohol, and obesity are all risk factors associated with the development of esophageal cancer. Table 42.4 shows the additional risk factors associated with esophageal cancer and their contributions to the development of either squamous cell carcinoma or adenocarcinoma.

Although many have postulated a genetic predisposition to esophageal cancer, tylosis is the only recognized familial syndrome that predisposes to the development of esophageal cancer. This is an autosomal dominant disorder that has been mapped to chromosome 17q25.³² Patients have hyperkeratosis of the palms of their hands and the soles of their feet. The risk of developing squamous cell carcinoma of the esophagus by age 70 is 95% in this cohort of patients.³³

Diagnosis

Unfortunately, early esophageal carcinomas are largely asymptomatic. As a distensible muscular tube, a significant portion of the esophageal lumen must be obstructed to impede passage of a food bolus and produce symptoms. Dysphagia is the primary manifestation of esophageal cancer in 80% of patients, and up to 20% have odynophagia. Vague symptoms of retrosternal discomfort and transient dysphagia are often overlooked by the patient and the physician. On retrospective evaluation, many patients have significantly altered their eating habits by avoiding foods such as meats and breads while increasing their intake of semisolid foods and liquids. About one half of patients have significant weight loss. Weight loss of more than 10% of body mass is an independent predictor of poor prognosis.³⁴

Pulmonary symptoms may be caused by aspiration of regurgitated food or by direct invasion of the airway by esophageal tumor. Direct airway invasion can occur with locally advanced lesions at the location where the left mainstem bronchus passes anterior to the esophagus. New hoarseness due to vocal cord paralysis is indicative of left recurrent nerve involvement and suggests unresectability. The Virchow node, a palpable left supraclavicular lymph node, may be apparent in some patients. Fine-needle aspiration with positive cytology confirms the pathologic involvement of the Virchow node, which is considered distant metastatic disease and precludes resection.

The evaluation of a patient with suspected esophageal cancer involves securing the diagnosis, clinically staging the patient, and determining the medical operability of patients with stage-appropriate lesions for resection. Barium swallow and esophagoscopy remain the most important diagnostic tools for assessing the patient with esophageal symptoms. Barium swallow is usually the first study obtained. It provides both anatomic and functional information. Flexible esophagoscopy is used to precisely locate the lesion and provide tissue confirmation of malignancy. In patients considered for surgical resection, endoscopic ultrasonography (EUS) is the single most

valuable test in determining tumor size and depth of penetration (T stage). EUS successfully predicts the T stage in greater than 80% of cases confirmed at surgery and generally performs better for advanced (T4) than local (T1) disease. Regional lymph nodes are also visualized during EUS and can be sampled by FNA to determine the cytologic presence or absence of metastatic nodal disease (N stage). The sensitivity of EUS alone to predict N stage is 85% and improves to greater than 95% with FNA.³⁵ Figure 42.10 shows an example of EUS for esophageal cancer.

A computed tomographic (CT) scan of the chest, abdomen, and pelvis with intravenous contrast is valuable for assessing lung and liver metastasis. However, it is not accurate for determining T stage or assessing regional lymph node involvement.

Positron emission tomography (PET) with 18 F-fluorodeoxyglucose (FDG) is a physiologic test unique in its ability to detect increased metabolic activity within tissues. It is increasingly used to detect distant metastasis (M stage) in patients with esophageal cancer. It has been reported that PET will detect otherwise radiographically occult metastatic disease in up to 15% of patients who were thought to have only localized disease by conventional studies, thus making them more appropriately managed by non-surgical interventions.³⁶ We now routinely obtain a PET scan as part of the preoperative staging evaluation in patients under consideration for esophagectomy. Increasingly, PET is being used to restage patients and evaluate response after neoadjuvant chemoradiation. Several studies have shown promising results in demonstrating that decreased FDG-avidity after neoadjuvant therapy predicts pathologic response and increased survival.^{37,38}

The use of combined thoracoscopy and laparoscopy for preoperative staging has been advocated by some centers. Periesophageal mediastinal lymph nodes and celiac lymph nodes can be sampled with a high degree of accuracy using these techniques.³⁹ This practice has largely been replaced by the combination of EUS-FNA and PET. We currently do not use these techniques as part of our standard evaluation.

Unfortunately, no serum tumor markers have been consistently found in patients with esophageal cancers. Standard serum cancer markers including CEA, CA 19-9, and CA 125 have no value in the preoperative evaluation of patients with esophageal cancer.

Adenocarcinoma. Adenocarcinoma of the esophagus was once considered rare; however, adenocarcinoma of the esophagus currently accounts for more than 50% of the esophageal cancers diagnosed in the United States and Western Europe. Obesity and Barrett, or columnar-lined esophagus, are associated with an increased risk of developing adenocarcinoma of the esophagus. Chronic gastroesophageal reflux disease (GERD) is considered the predominant contributor to the development of Barrett metaplasia. The frequency, severity, and duration of reflux symptoms are correlated with an increased risk of developing esophageal adenocarcinoma.⁴⁰ Patients with recurring symptoms of reflux have an eightfold increase in the risk of esophageal adenocarcinoma.

A Barrett esophagus develops in about 5% of patients with GERD. Endoscopically, it is recognized by inflamed salmon-colored mucosa extending proximally from the GE junction. Often there are intervening areas of normal-appearing mucosa,

FIGURE 42.10. Endoscopic image (A) and endoscopic ultrasound (B) showing a transmural adenocarcinoma of the esophagus associated with a Barrett esophagus (*short arrows*), with lymph node metastasis (*long arrow*). or so-called skip areas. Figure 42.11A shows the typical endoscopic appearance; Figure 42.11B shows the same patient with methylene blue vital stain, which can be used to highlight the mucosal changes. Microscopic evaluation reveals replacement of the normal stratified squamous epithelium of the esophagus with columnar epithelium more typical of other parts of the gastrointestinal tract. Thus, these changes are often referred to

as “intestinalization” of the mucosa. With progression to dysplasia, the nuclei become crowded and the normal glandular architecture is lost. Histologically, patients with high-grade dysplasia carry a significant risk for esophageal carcinoma and should be considered candidates for resection. Ten percent to thirty percent of patients with high-grade dysplasia will develop invasive adenocarcinoma within 5 years of the initial

FIGURE 42.11. A: The typical endoscopic appearance of Barrett changes at the gastroesophageal (GE) junction. Note the salmon-colored areas of erosion extending from the GE junction. Also note the intervening areas of normal appearing mucosa. B: Vital staining with methylene blue. Vital stains are used to highlight the mucosal changes at the time of endoscopy. (Courtesy of Michael L. Kochman, M.D., University of Pennsylvania, Philadelphia.)

diagnosis; moreover, in patients undergoing esophagectomy for presumed high-grade dysplasia, invasive carcinoma is identified in 30% to 40% of the pathologic specimens.⁴¹ A Barrett esophagus increases the risk of esophageal adenocarcinoma when compared with the general population.⁴² The annual rate of neoplastic transformation to adenocarcinoma in patients with Barrett is 0.5%.⁴³

Squamous Cell Carcinoma. The primary risk factor for squamous cell carcinoma of the esophagus is chronic irritation of the esophageal mucosa. Prolonged alcohol consumption, especially in combination with tobacco exposure, appears to be the major contributing factor. Nitrosamines and other nitrosyl compounds found in smoked meats are also important factors in native populations who rely on them for their main source of nutrition. In some Asian countries, there appears to be strong correlation between the development of squamous cell cancer of the esophagus and ingestion of hot beverages. Medical conditions including achalasia, caustic strictures, Plummer-Vinson syndrome, and tylosis also increase the risk of squamous cell carcinoma. Patients with tylosis have a 40% lifetime incidence of squamous cell carcinoma of the esophagus.³² The risk with long-standing achalasia approximates 7%.⁴⁴

Staging of Esophageal Cancers

Esophageal cancers are staged according to the American Joint Committee on Cancer (AJCC) TNM staging system.⁴⁵ The current (sixth edition) AJCC definitions are shown in Table 42.5. The stage groupings and current recommended treatment strategy for each stage are displayed in Table 42.6. The staging system for esophageal cancer has recently undergone revision and should be published soon. Pathologic stage according to the updated system will be dependent on the number of nodes containing metastasis, tumor grade, tumor location, and histologic cell type.

It is clear that the outcome in esophageal cancer is strongly associated with the stage of the disease. Thus, accurate clinical staging is of paramount importance in formulating an appropriate treatment plan and providing the patient with information regarding prognosis. The preoperative evaluation is intended to define the extent of disease and thus the clinical stage. All patients should have a CT scan of the chest and abdomen. In the absence of lung, liver, or other distant metastatic disease, EUS is performed to define the depth of tumor invasion and assess regional lymph nodes. Recently, we have added PET scanning to the standard preoperative evaluation as PET is a complementary modality to the CT scan and in conjunction with CT is very sensitive at detecting distant metastatic disease. In stage-appropriate candidates, plans are made to optimize the patient from a medical standpoint and proceed to resection. The role of preoperative therapy followed by operation remains ill defined and hotly debated.

Neoadjuvant Therapy

The current information on neoadjuvant treatment can be divided into studies evaluating preoperative radiation, preoperative chemotherapy, and combined preoperative chemoradiation therapy. In operable patients with resectable tumors, the results of any preoperative therapy followed by resection must be compared with the results of primary resection alone. It is important that this analysis must take into account the toxicities associated with multimodality therapy and the impact on the intended resection and quality of life.

Several randomized trials have failed to show any benefit from preoperative radiation therapy alone. Proponents of preoperative radiotherapy argue that the trials are too small to demonstrate the advantages of this approach. A meta-analysis

TABLE 42.5

STAGING

AMERICAN JOINT COMMITTEE ON CANCER (AJCC) STAGING OF ESOPHAGEAL CANCER

■ STAGE	■ DESCRIPTION
PRIMARY TUMOR (T)	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ
T1	Tumor invades lamina propria or submucosa
T2	Tumor invades muscularis propria
T3	Tumor invades adventitia
T4	Tumor invades adjacent structures
REGIONAL LYMPH NODES (N)	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Regional lymph node metastasis
DISTANT METASTASIS (M)	
MX	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis
TUMORS OF THE LOWER THORACIC ESOPHAGUS	
M1a	Metastasis in celiac lymph nodes
M1b	Other distant metastasis
TUMORS OF THE MIDTHORACIC ESOPHAGUS^a	
M1a	Not applicable
M1b	Nonregional lymph nodes and/or other distant metastasis
TUMORS OF THE UPPER THORACIC ESOPHAGUS	
M1a	Metastasis in cervical nodes
M1b	Other distant metastasis

^aFor tumors of midthoracic esophagus, use only M1b because these tumors with metastasis in nonregional lymph nodes have an equally poor prognosis as those with metastasis in other distant sites. of available randomized trials comprising 1,147 patients, however, found no improvement in survival with preoperative radiotherapy alone in patients with resectable esophageal cancer.⁴⁶ At this time, there is no indication for preoperative radiation therapy alone followed by resection.

The utility of preoperative chemotherapy alone is much more poorly defined. A large multicenter randomized trial in the United States (Intergroup Trial) of 440 patients failed to show any improvement in survival after three cycles of combined cisplatin and fluorouracil followed by surgery and two postoperative cycles when compared to surgery alone.⁴⁷ This is in contrast to a large randomized European study (Medical Research Council), which suggested that neoadjuvant chemotherapy resulted in nearly a 10% improvement in survival at 2 years.⁴⁸ Unfortunately, the preoperative staging techniques and duration of treatments were quite different, making the two studies difficult to compare. More recently, another European neoadjuvant chemotherapy trial (MAGIC trial) demonstrated improved survival with perioperative chemotherapy versus surgery alone (36% vs. 23% at 5 years).⁴⁹ Of note, 75% of the MAGIC trial participants had gastric cancer, while

chemo, chemotherapy; XRT, radiation therapy.

only 25% had either distal esophageal or GE junction adenocarcinoma. Also, only 41.6% of patients randomized to perioperative chemotherapy were able to complete all six prescribed cycles of therapy. In the most recent Cochrane review of the topic, 11 randomized controlled trials with 2,051 patients suggested that preoperative chemotherapy plus surgery may offer a survival advantage compared to surgery alone for resectable esophageal cancer.⁵⁰ There was no demonstrable difference in the rate of resection, tumor recurrence, or postoperative morbidity. There was some chemotherapy-related morbidity. Presumably based on the relative success of the MRC and MAGIC trials, chemotherapy alone is used quite commonly as neoadjuvant therapy in Europe, whereas combined chemotherapy and radiation is used more commonly in the United States.

Several small randomized trials have evaluated combined preoperative chemoradiation followed by surgical resection. The most widely cited trial to justify the use of combined treatment followed by surgery was published by Walsh et al.⁵¹ in 1996. This study projected a 3-year survival of 32% in the neoadjuvant treatment group as compared to 6% in the surgery alone group for patients with adenocarcinoma. Critics were quick to point out the lack of appropriate staging, the poor survival in the surgical group as compared with other surgical series, and the small study size. A more recent study found equivalent median and 3-year survival in patients with squamous cell carcinoma of the esophagus randomized to either preoperative chemoradiation followed by surgery or surgery alone.⁵² An increased complication rate was noted in the patients undergoing preoperative chemoradiation therapy. A recent meta-analysis of 10 randomized controlled trials of neoadjuvant chemoradiotherapy versus surgery alone demonstrated an absolute survival advantage of 13% at 2 years favoring neoadjuvant therapy.⁵³ Despite a paucity of conclusive data, there seems to be an evolving consensus at most centers that patients with T3 and/or N1 disease should receive neoadjuvant chemoradiation. This issue remains unresolved, and operation remains the standard treatment for localized

esophageal cancer outside of a clinical trial. At this time we consider neoadjuvant chemoradiotherapy to be investigational. Unfortunately, a large intergroup trial designed to answer this question was closed because of poor accrual.

Operative Management

Approaches to Esophagectomy. There are several surgical approaches to esophagectomy. Selecting the appropriate procedure for an individual patient depends on the overall medical condition of the patient, the location of the tumor, and the expertise and experience of the surgeon. Possible approaches include the transhiatal approach, the transabdominal transthoracic approach (Ivor Lewis), the three-stage or “three-hole” approach (McKeown), the thoracoabdominal approach, and the minimally invasive approach. Options for reconstruction include a gastric tube, a colonic interposition, and in selected cases small intestinal free graft. Because of its ample blood supply, ease of mobilization, and sufficient length to reach the neck, the gastric tube is the usual conduit of choice for reconstruction. The use of colon is more complex and has increased morbidity when compared to gastric pull-up.⁵⁴ We reserve the use of colon or jejunum for patients with an unusable stomach due to previous surgery, tumor extension, or other technical considerations.

The esophageal anastomosis requires meticulous attention. Many esophageal operations are plagued by high anastomotic leak rates and a significant number of postoperative strictures. At present, the modified stapled anastomosis as described by Orringer et al.⁵⁵ appears to have the lowest leak rate, about 3% as compared with sutured techniques, which are as high as 15%. The technique is shown in Figure 42.12; many thoracic surgeons have adopted this anastomotic technique.

The Transhiatal Approach. The transhiatal esophagectomy was reintroduced by Orringer and Sloan² in 1978 and continues to be refined.^{56,57} The procedure is performed through an

FIGURE 42.12. The stapled technique for cervical esophageal anastomosis. This technique results in lower anastomotic leak rates and fewer postoperative strictures. (Adapted with permission from Orringer MB, Marshall B, Iannettoni MD. Eliminating the cervical esophago-gastric anastomotic leak with a side-to-side stapled anastomosis. *J Thorac Cardiovasc Surg* 2000;119:277.)

upper midline laparotomy and left cervical incision as shown in Figure 42.13. A gastric conduit based on the right gastroepiploic artery is used to establish gastrointestinal continuity. The completed operation is depicted in Figure 42.14. If the stomach is unusable, a colonic interposition can be performed.

Today, the transhiatal esophagectomy is the preferred approach by many surgeons. Nevertheless, debate continues over whether this approach has lower morbidity and mortality than other approaches involving thoracotomy and whether it provides an optimal cancer operation. Proponents argue that this approach results in less surgical trauma by avoiding thoracotomy and thus less postoperative morbidity, especially pulmonary complications. Furthermore, with placement of the anastomosis in the neck, a leak, should it occur, can be treated by simple bedside cervical drainage. In contrast, a leak in the chest is far more likely to result in severe mediastinitis and more devastating complications.

The Ivor Lewis Approach. The transabdominal transthoracic approach to esophagectomy as initially described is often referred to as the Ivor Lewis esophagectomy.³ This approach includes an upper midline laparotomy for mobilization of the stomach with creation of a gastric tube in the same manner used for the transhiatal esophagectomy. Once the stomach has been mobilized, the hiatus is opened and the GE junction and distal esophagus are mobilized. At this point the abdomen is closed, the patient is repositioned, and a right fifth intercostal space thoracotomy is performed. The intrathoracic esophagus is mobilized under direct vision up to the level of the azygous vein. The esophagogastric anastomosis is performed at the level of the divided azygous vein. The advantage of this approach is that the intrathoracic esophagus is mobilized directly with full exposure of the mediastinum and surrounding structures. This may be of value in avoiding injury to the airway or other mediastinal structures, especially with bulky tumors in the middle third of the esophagus at the level of the carina. Unfortunately, these patients are subject to increased early postoperative pulmonary complications due to the thoracotomy incision. In addition, placing the anastomosis in the

chest can lead to life-threatening mediastinitis should an anastomotic leak occur. Additionally, a large amount of thoracic esophagus is retained with this approach and may be at risk of recurrent disease, specifically in the setting of severe Barrett esophagus.

Three-Field Esophagectomy. This approach is carried out through separate laparotomy, right thoracotomy, and cervical incisions.⁴ Proponents of this approach fall into two categories. The first group uses this approach to resect large intrathoracic lesions of the midesophagus. Exposure especially at the level of the carina and left mainstem bronchus is superior as compared with the transhiatal approach. Because visualization is improved, the injury rate to nearby structures, especially the airway and azygous vein, is lower. The second group uses this approach to perform a complete two- or three-field lymph node dissection, suggesting that this approach provides a more complete resection and thus improves long-term survival. This approach has been shown to have acceptable morbidity and mortality as compared with other approaches; however, the often-cited report was from a single U.S. center.⁵⁸ On the other hand, a large randomized Dutch trial comparing transhiatal resection with extended transthoracic resection showed that the transhiatal approach was associated with a lower morbidity and no statistically different overall, disease-free, and quality-adjusted survival.⁵⁹ Patients who underwent thoracotomy had an increased incidence of chyle leak and pulmonary complications, as well as longer ventilator dependence, ICU stay, and hospital stay (Table 42.7). In a recent retrospective review of 2,303 esophageal cancer patients treated with R0 resection without adjuvant or neoadjuvant therapy, the number of nodes removed was an independent predictor of survival. The authors concluded that to maximize this survival benefit, a minimum of 23 nodes should be removed at esophagectomy.⁶⁰ The true value of extensive lymphadenectomy in esophageal cancer remains undefined.

The Thoracoabdominal Approach. The left thoracoabdominal approach is probably the least used of all approaches to

FIGURE 42.13. **A:** Transhiatal mobilization of the thoracic esophagus from the posterior mediastinum with the use of blunt dissection and traction on rubber drains placed around the esophagogastric junction and cervical esophagus. The volar aspects of the fingers are kept against the esophagus to reduce the risk for injury to adjacent structures. **B:** Lateral view showing transhiatal mobilization of the esophagus away from the posterior mediastinum. Half of a sponge on a stick is inserted through the cervical incision and advanced until it makes contact with the hand inserted from below through the diaphragmatic hiatus. Arterial pressure is monitored as the heart is displaced forward by the hand in the posterior mediastinum. (Adapted with permission from Orringer MB. Surgical options for esophageal resection and reconstruction with stomach. In: Baue AE, Geha AS, Hammond GL, eds. *Glenn's Thoracic and Cardiovascular Surgery*, 5th ed. Norwalk, CT: Appleton & Lange; 1991:799.)

the esophagus. It is performed by making an oblique incision from the midpoint between the xiphoid and umbilicus across the costal arch to the tip of the scapula. The abdomen is opened, the costal arch is divided, and the chest is entered through the seventh intercostal space. The diaphragm is opened in a circumferential manner along the chest wall to avoid any damage to the phrenic nerve branches. At least a 2-cm rim of diaphragm is preserved on the chest wall to aid in reconstruction of the diaphragm at the completion of the procedure. This approach offers superior exposure to the left upper quadrant, including the hiatus, and is our approach of choice in patients with previous extensive hiatal or proximal gastric surgery. For patients with distal tumors and inadequate conduit for total esophageal replacement, the anastomosis can be placed in the left chest below the inferior pulmonary vein or up to the level of the aortic arch. For those with adequate conduit, a separate left cervical incision can be made and the cervical esophagogastric anastomosis can be placed in the neck. A consecutive case series of 64 thoracoabdominal esophagec-

tomies reported no anastomotic leaks and a 2% mortality rate.⁶¹

The Minimally Invasive Approach. Various minimally invasive techniques to esophagectomy have been described. These include laparoscopic, hand-assisted, thoracoscopic, and robotic-assisted esophagectomy. The hope of these procedures is that minimizing the incision size will decrease the morbidity of the operation while at the same time providing adequate resection. The largest study included 217 patients from the University of Pittsburgh who underwent esophagectomy via thoracoscopy, laparoscopy, and a left neck incision.⁶² The investigators observed equivalent results as compared to open techniques and suggest development of a multicenter trial to define the role of minimally invasive esophagectomy. At present, the advantage of this approach remains to be determined.

Cervical Esophageal Cancer. Cervical esophageal cancer represents a very small subset of primary esophageal cancers.

FIGURE 42.14. Final position of the mobilized stomach in the posterior mediastinum after transhiatal esophagectomy and cervical esophago-gastric anastomosis. The gastric fundus has been suspended from the cervical prevertebral fascia, and an end-to-side cervical esophago-gastrostomy has been performed. The pylorus is now located several centimeters below the level of the diaphragmatic hiatus. (Adapted with permission from Orringer MB, Sloan H. Esophagectomy without thoracotomy. *J Thorac Cardiovasc Surg* 1978;76:643.)

Direct extension into the cervical esophagus from a primary laryngeal or thyroid malignancy is much more common. Unfortunately, all are difficult to treat. Traditional methods of treatment have relied on definitive chemoradiation therapy. A small subset of patients may be candidates for salvage resection, which usually includes laryngectomy with permanent tracheostomy, esophagectomy, and gastric transposition to reconstitute the gastrointestinal tract.

Palliation

Several palliative therapies are available for patients who have unresectable disease, have metastatic disease, or are medically unfit for surgery. The intent of palliation is to maintain comfort, restore swallowing function if possible, and support nutrition.

Establishment of alternative enteral access is helpful in maintaining nutritional status and hydration. When possible, this is provided by a percutaneous gastrostomy (PEG) tube placed under endoscopic guidance. For patients with bulky obstructing lesions who cannot undergo PEG, an open gastrotomy or jejunostomy tube is required.

Chemotherapy. Esophageal cancers are usually responsive to chemotherapeutic drugs providing some palliation. Agents currently in use include fluorouracil and taxanes either alone or in combination with platin-based agents. Palliative chemotherapy requires time to effectively reduce symptoms of dysphagia and must be balanced with the associated risks of systemic treatment in usually debilitated, malnourished patients.

Radiation. Palliative radiotherapy relieves dysphagia in up to 75% of patients. The dose is 4,000 to 5,000 cGy delivered over 4 weeks. This allows patients with advanced disease and severe dysphagia to handle secretions and to swallow liquids as well as dietary supplements. Unfortunately, relief is not immediate and maximal improvement occurs at about 4 weeks following completion of treatment. In patients with a life expectancy greater than 3 months, combined chemotherapy with radiation is used. Short-term side effects from radiation therapy include skin irritation and erythema. Esophagitis with painful swallowing also occurs with frequency. Additional complications include stricture formation, radiation pneumonitis, and fistulization to the airway.

Stenting. Palliative endoscopic intubation of inoperable malignant esophageal strictures was first described in the 1970s.¹⁷ Currently, self-expanding coated and uncoated nitinol stents are used for palliation. These stents can be inserted either radiologically or endoscopically on an outpatient basis. Following insertion, the lumen can be balloon dilated to an acceptable diameter to provide palliation.

Neodymium:Yttrium-Aluminum-Garnet Laser Fulguration. Endoscopic neodymium:yttrium-aluminum-garnet (Nd:YAG) laser fulguration can be used to provide temporary relief of esophageal obstruction in patients with unresectable obstructing tumors. A flexible quartz fiber is passed through the working channel of the esophagoscope to deliver the laser energy at the fiber tip. Multiple sessions are usually required to achieve debulking and functional success. Laser fulguration is often combined with endoluminal stenting and radiation therapy. It can also be useful in patients who have undergone uncovered stenting procedures with ingrow of tumor through the stent.

Photodynamic Therapy. Intraluminal photodynamic therapy (PDT) is a nonthermal ablative technique that can be used to palliate patients. This technique requires the systemic administration of a hematoporphyrin, which is concentrated within the malignant cells. Approximately 48 hours after administration of the photosensitizer, patients undergo endoscopy and an argon-pump dye-laser is used to deliver endoluminal light at a wavelength of 630 nm. This results in the generation of oxygen radicals, which quickly lead to tumor necrosis. The depth of penetration is relatively limited, and this decreases the risk of full-thickness necrosis with perforation. Unfortunately, the photosensitizing agents are retained by the reticuloendothelial system in skin; thus, patients are sensitive to infrared wavelength light, including sunlight, radiant heat, fluorescent light, and strong incandescent light. Depending on the photosensitizing agent used, this sensitivity can persist up to 3 months, a challenging problem in patients with short life expectancies.

A recent series of 215 patients treated with palliative endoluminal PDT revealed a procedure-related mortality rate of 1.8%, effective palliation for patients with obstructing cancers in 85% of the treatment courses, and median survival of 4.8 months.⁶³ Some patients in this series also required stenting, suggesting that PDT has a role in multimodality palliation of obstructing esophageal cancers.

TABLE 42.7

COMPLICATIONS

	■ TRANSTHORACIC (n = 114)	■ TRANSHIATAL (n = 106)	■ P VALUE
Pulmonary complications	57%	27%	<0.001
Chylothorax	10%	2%	0.02
Ventilator time (days)			<0.001
Median	2	1	
Range	0–76	0–19	
Intensive care unit stay (days)			<0.001

CHAPTER 43 ■ GASTRIC ANATOMY AND PHYSIOLOGY

MICHAEL W. MULHOLLAND

KEY POINTS

- 1 The stomach is an extremely well-vascularized organ, supplied by a number of major arteries and protected by a large number of extramural and intramural collaterals.
- 2 Oxyntic glands occupy the fundus and body of the stomach and contain the oxyntic or parietal cells, which are the sites of acid production. Oxyntic glands also contain chief cells, the site of gastric pepsinogen synthesis.
- 3 The most important stimulant of gastrin release is a meal. Postprandial luminal pH also strongly affects gastrin secretion.
- 4 Ghrelin is the only known circulating hormone that causes the sensation of hunger and stimulates oral intake.
- 5 The basolateral membrane of the parietal cell contains specific receptors for histamine, gastrin, and acetylcholine, the three major stimulants of acid production.
- 6 Pepsins are a heterogeneous group of proteolytic enzymes that are secreted by the gastric chief cells.
- 7 The gastric mucosa is the site of production of intrinsic factor, which is necessary for the absorption of cobalamin from the ileal mucosa. Total gastrectomy is regularly followed by cobalamin malabsorption, as is resection of the proximal stomach or atrophic gastritis that involves the oxyntic mucosa.

GROSS ANATOMY

The stomach and duodenum, along with the esophagus, liver, bile ducts, and pancreas, are derived from the embryonic foregut. During the fifth week of gestation, the future stomach is marked as a dilation in the caudal portion of the foregut. Cranial to this dilation, the trachea forms as a bud from the future esophagus. At this time, the primitive stomach is invested with both ventral and dorsal mesenteries. The embryonic ventral mesentery is represented in postnatal life by the falciform ligament and by the gastrohepatic and hepatoduodenal mesenteries that form the lesser omentum. The celiac artery, the major blood supply to the foregut, passes within the dorsal mesentery. The primitive dorsal mesentery ultimately forms three structures: the gastrocolic ligament, the gastrosplenic ligament, and the gastrophrenic ligament.

During the sixth and seventh weeks of gestation, the typical morphology of the stomach is established. Accelerated growth of the left gastric wall, relative to the right, establishes the greater and lesser curvatures. This unequal growth also rotates the stomach and causes the left vagal nerve trunk to assume its anterior position, whereas the right vagal trunk is located posteriorly. The growth of structures cephalad to the stomach causes the organ to descend. During the sixth week, the primitive stomach lies between the T10 and T12 vertebral segments. By the eighth week, the stomach is located between the T11 and the L4 segments. In adult life, the stomach is most commonly located between the T10 and the L3 vertebral segments.

The stomach can be divided into anatomic regions based on external landmarks (Fig. 43.1). Although this division is commonly referred to in surgical texts and is useful in discussing gastric resective procedures, it does not necessarily reflect the secretory or motor functions of the mucosal and muscular layers of the stomach. The gastric cardia is the region of the stomach just distal to the gastroesophageal junction. The fundus is the portion of the stomach above and to the left of the gastroesophageal junction. The corpus constitutes the region between the fundus and the antrum. The mar-

gin between the corpus and antrum is not distinct externally but can be defined arbitrarily by a line from the incisura angularis on the lesser curvature to a point one-fourth the distance from the pylorus to the esophagus along the greater curvature. The gastric antrum is bounded distally by the pylorus, which can be appreciated by palpation as a thickened ring of smooth muscle.

The stomach is mobile in most people and is fixed at only two points, proximally by the gastroesophageal junction and distally by the retroperitoneal duodenum. Therefore, the position of the stomach varies and depends on the habitus of the person, the degree of gastric distention, and the position of the other abdominal organs. Anteriorly, the stomach is in contact with the left hemidiaphragm, the left lobe and the anterior segment of the right lobe of the liver, and the anterior parietal surface of the abdominal wall. The posterior surface of the stomach is related to the left diaphragm; the left kidney and left adrenal gland; the neck, tail, and body of the pancreas; the aorta and celiac trunk; and the periaortic nerve plexuses. The greater curvature of the stomach is near the transverse colon and the transverse colonic mesentery. The concavity of the spleen contacts the left lateral portion of the stomach.

- 1 The stomach is an extremely well-vascularized organ, supplied by a number of major arteries and protected by a large number of extramural and intramural collaterals. Gastric viability can be preserved after ligation of all but one primary artery, an advantage that can be exploited during gastric reconstructive procedures. Also, the rich network of anastomosing vessels means that gastric hemorrhage cannot be controlled by the extramural ligation of gastric arteries. Most gastric blood flow is ordinarily derived from the celiac trunk (Fig. 43.2). The lesser curvature is supplied by the left gastric artery, which is the first major branch of the celiac trunk, and by the right gastric artery, which is derived from the hepatic artery. Branches of the left gastric artery also supply the lowermost portion of the esophagus. The greater curvature is supplied by the short gastric and left gastroepiploic arteries, which are branches of the splenic artery, and by the right gastroepiploic

FIGURE 43.1. Topographic relations of the stomach.

artery, a branch of the gastroduodenal artery. In instances of celiac trunk occlusion, gastric blood flow is usually maintained from the superior mesenteric artery collaterally by way of the pancreaticoduodenal arcade. In general, venous effluent from the stomach parallels the arterial supply. The venous equivalent of the left gastric artery is the coronary vein.

As a first approximation, the lymphatic drainage of the stomach parallels gastric venous return (Fig. 43.3). Lymph from the proximal portion of the stomach along the lesser curvature first drains into superior gastric lymph nodes surrounding the left gastric artery. The distal portion of the lesser cur-

vature drains through suprapyloric nodes. The proximal portion of the greater curvature is supplied by lymphatic vessels that traverse pancreaticosplenic nodes, whereas the antral portion of the greater curvature drains into the subpyloric and omental nodal groups. Secondary drainage from each of these systems eventually traverses nodes at the base of the celiac axis. These discrete anatomic groupings are misleading. The lymphatic drainage of the human stomach, like its blood supply, exhibits extensive intramural ramifications and a number of extramural communications. As a consequence, disease processes that involve the gastric lymphatics often spread

FIGURE 43.2. Arterial blood supply of the stomach.

FIGURE 43.3. Lymphatic drainage of the stomach.

intramurally beyond the region of origin and to nodal groups at a distance from the primary lymphatic zone.

The left and right vagal nerves descend parallel to the esophagus within the thorax before forming a periesophageal plexus between the tracheal bifurcation and the diaphragm. From this plexus, two vagal trunks coalesce before passing through the esophageal hiatus of the diaphragm (Fig. 43.4). The left vagal trunk is usually closely applied to the anterior surface of the esophagus, whereas the posterior vagal trunk is often midway between the esophagus and the aorta. The anterior vagus supplies a hepatic division, which passes to the right in the lesser omentum before innervating the liver and biliary tract. The remainder of the anterior vagal fibers parallel the lesser curvature of the stomach, branching to the anterior gas-

tric wall. The posterior vagus nerve branches into the celiac division, which passes to the celiac plexus, and a posterior gastric division, which innervates the posterior gastric wall.

Approximately 90% of the fibers in the vagal trunks are afferent, transmitting information from the gastrointestinal tract to the central nervous system (CNS). Parasympathetic afferent fibers are not responsible for the sensation of gastric pain. Only 10% of vagal nerve fibers are motor or secretory efferents. Parasympathetic efferent fibers contained in the vagus originate in the dorsal nucleus of the medulla. Vagal efferent fibers pass without synapse to contact postsynaptic neurons in the gastric wall in the myenteric and submucous plexuses. Secondary neurons directly innervate gastric smooth muscle or epithelial cells. Acetylcholine is the neurotransmitter of primary vagal efferent neurons.

The gastric sympathetic innervation is derived from spinal segments T5 through T10. Sympathetic fibers leave the corresponding spinal nerve roots by way of gray rami communicantes and enter a series of bilateral prevertebral ganglia (Fig. 43.5). From these ganglia, presynaptic fibers pass through the greater splanchnic nerves to the celiac plexus, where they synapse with secondary sympathetic neurons. Postsynaptic sympathetic nerve fibers enter the stomach in association with blood vessels. Afferent sympathetic fibers pass without synapse from the stomach to dorsal spinal roots. Pain of gastroduodenal origin is sensed through afferent fibers of sympathetic origin.

**FIGURE 43.4.** Vagal innervation of the stomach.

MICROSCOPIC ANATOMY

The glandular portions of the stomach are lined by a simple columnar epithelium composed of surface mucous cells. The luminal surface, visualized by scanning electron microscopy, appears cobblestoned, interrupted at intervals by gastric pits. Opening into the gastric pits are one or more gastric glands that impart functional significance to the gastric mucosa. The mucosa of the human stomach is composed of three distinct types of gastric glands—cardiac, oxyntic, and antral.

FIGURE 43.5. Derivation of gastric sympathetic innervation.

In humans, cardiac glands occupy a narrow zone adjacent to the esophagus and mark a transition from the stratified squamous epithelium of the esophagus to the simple columnar epithelium of the stomach. The surface and gastric pit mucous cells of the cardia are not distinguishable from those in other areas of the stomach. Cardiac glands contain mucous and undifferentiated and endocrine cells but not the parietal or chief cells that are prominent in the adjacent oxyntic mucosa. Cardiac glands are usually branched and connect with relatively short gastric pits. The functional properties of cardiac glands include the secretion of mucus.

2 Oxyntic glands are the most distinctive feature of the human stomach. They occupy the fundus and body of the stomach and contain the oxyntic or parietal cells, which are the sites of acid production. Oxyntic glands also contain chief cells, the site of gastric pepsinogen synthesis. The tubular oxyntic glands are usually relatively straight but sometimes branch; several glands may empty into a single gastric pit. The glands are divided into three regions: (a) the isthmus, containing surface mucous cells and a few scattered parietal cells; (b) the neck, with a heavy concentration of parietal cells and a few neck mucous cells; and (c) the base of the gland, containing chief cells, undifferentiated cells, a few parietal cells, and some mucous neck cells. Endocrine cells are scattered throughout all three regions of oxyntic glands.

The most distinctive cell of the gastric mucosa is the acid-secreting parietal cell. Parietal cells have an unusual ultrastructural specialization in the form of intracellular canaliculi, a network of clefts extending to the basal cytoplasm and often encircling the nucleus, which is continuous with the gland lumen (Fig. 43.6). The surface area provided by the intracellular

FIGURE 43.6. Resting and stimulated parietal cell, emphasizing morphologic transformation with increase in secretory canalicular membrane surface area that occurs with acid secretion.

secretory canaliculi is large and is further magnified by microvilli lining the canaliculi. In parietal cells that are not stimulated to secrete acid, the secretory canaliculi are collapsed and inconspicuous. On stimulation, a severalfold increase in canalicular surface area occurs, the intracellular clefts become prominent, and the communication with the luminal surface is readily identified. These changes create an intracellular space in communication with the gastric lumen into which hydrogen ions are secreted at high concentration.

The cytoplasm of the parietal cell also contains an abundance of large mitochondria. Mitochondria are estimated to occupy 30% to 40% of the cytoplasmic volume of unstimulated parietal cells, reflecting the extremely high oxidative activity of these cells. The oxygen consumption rate of isolated parietal cells is approximately five times higher than that of gastric mucous cells. The cytoplasm also contains a limited amount of rough endoplasmic reticulum, presumed to be the production site of intrinsic factor, which is also secreted by parietal cells.

In addition to parietal cells, the oxyntic glands contain the gastric chief cells, which synthesize and secrete pepsinogen. Chief cells are most abundant in the basal region of the oxyntic glands. The cells have a morphology typical of protein-secreting

FIGURE 43.7. Contrasting morphology of antral gastrin cell (*left*) with basally oriented secretory granules, and gastric mucous cell (*right*) with apical mucous granules.

exocrine cells and are similar in ultrastructural appearance to pancreatic acinar cells. Rough endoplasmic reticulum is abundant in the cytoplasm and extends between secretory granules. Zymogen granules containing pepsinogen are most concentrated in the apical cytoplasm. Pepsinogen is released by exocytosis from secretory granules at the apical surface of chief cells.

Antral glands occupy the mucosa of the distal stomach and pyloric channel. Antral glands are relatively straight and often empty through deep gastric pits. Although most cells in the antral glands are mucus secreting, gastrin cells are the distinctive feature of this mucosa. Gastrin cells are pyramid shaped, with a narrow area of luminal contact apically and a broad surface overlying the lamina propria basally (Fig. 43.7). Gastrin cells are identified immunocytochemically by the presence of the peptide. Granules ranging from 150 to 400 nm in diameter are the sites of gastrin storage and are most numerous in the basal cytoplasm. Gastrin is released by exocytotic fusion of the secretory granule with the plasma membrane. In contrast to secretion from chief cells, emptying of gastrin-containing granules occurs at the basal membrane rather than at the apical region of the cell. Gastrin thus released diffuses to and enters submucosal capillaries in close apposition to the lamina propria.

GASTRIC PEPTIDES

The stomach contains a number of biologically active peptides in nerves and mucosal endocrine cells, including gastrin, somatostatin, ghrelin, gastrin-releasing peptide, vasoactive intestinal polypeptide (VIP), substance P, glucagon, and calcitonin gene-related peptide. The peptides with the greatest importance to human disease and clinical surgery are gastrin, somatostatin, and ghrelin.

Gastrin

The synthesis, secretion, and action of gastrin have been extensively studied, and many aspects of the biology of gastrin appear to be shared by other gastrointestinal peptide hormones.¹ The gene that encodes for gastrin has been isolated using a human DNA library. The human gastrin gene contains three exons; two exons consist of coding sequences. The major active product is encoded by a single exon. In adults, the gastrin gene is expressed primarily in mucosa cells of the gastric antrum, with lower levels of expression in the duodenum, pituitary, and testis. During embryonic development, the gastrin gene is transiently active in pancreatic islets and colonic mucosa.

The human gene encompasses approximately 4,100 base pairs and directs the synthesis of a peptide of 101 amino acids (Fig. 43.8). The resulting peptide, preprogastrin, contains the sequence of gastrin within its amino acid sequence. Preprogastrin consists of a signal peptide of 21 amino acids, an intervening peptide of 37 amino acids, the 34-residue region of the gastrin molecule, and a carboxyl-terminal extension of nine amino acids. Gastrin is derived from its preprohormone by the sequential enzymatic cleavage of the signal peptide, the intervening peptide, and the carboxyl-terminal extension.

The signal peptide region of preprogastrin consists of a series of hydrophobic amino acids that direct the nascent peptide into the endoplasmic reticulum as it is translated from messenger RNA. After directing the preprogastrin molecule into the rough endoplasmic reticulum, the signal peptide is removed. The remaining peptide is termed *progastrin*. Progastrin is further processed as it traverses the endoplasmic reticulum to mature secretory vesicles. Enzymatic cleavage at a pair of basic amino acid residues proximal to the gastrin 34 (G₃₄) sequence removes the intervening peptide. A similar cleavage removes a six-amino-acid fragment at the carboxyl-terminal end. The peptide that remains has a Gly-Arg-Arg sequence at

FIGURE 43.8. Sequential processing of preprogastrin molecule.

the carboxyl terminus. Carboxypeptidase cleaves the Arg residues, and the peptide that results is termed *glycine-extended gastrin*. G_{34} is formed by cleavage of the Gly-Arg-Arg sequence and amidation of the carboxyl-terminal phenylalanine. Gastrin, like most gastrointestinal peptide hormones, requires terminal amidation for biologic activity. Gastrin 17 (G_{17}), the most abundant form of gastrin in the human antrum, is formed by further processing that removes the first 17 amino acids at the amino terminus of G_{34} . G_{34} is the predominate molecular form of gastrin in the duodenum.

3 The most important stimulant of gastrin release is a meal. Small peptide fragments and amino acids that result from intragastric proteolysis are the most important food components that stimulate gastrin release. The most potent gastrin-releasing activities are demonstrated by the amino acids tryptophan and phenylalanine. Ingested fat and glucose do not cause gastrin release. Gastric distention by a meal activates cholinergic neurons and stimulates gastrin release. As the meal empties and distention diminishes, VIP-containing neurons are activated, which stimulate somatostatin secretion and thus attenuate gastrin secretion.

Postprandial luminal pH also strongly affects gastrin secretion. Gastrin release is inhibited when acidification of an ingested meal causes the intraluminal pH to fall below 3.0. Conversely, maintaining intragastric pH above 3.0 potentiates gastrin secretion after ingestion of protein or amino acids.² Pernicious anemia and atrophic gastritis, which produce chronic achlorhydria, are associated with fasting hypergastrinemia and an exaggerated gastrin meal response. Release of mucosal somatostatin occurs with gastric acidification, and this peptide

has been implicated in the inhibition of gastrin release that occurs when luminal pH falls.

The vagus nerve appears to both stimulate and inhibit gastrin release.³ In humans, vagally mediated stimulation of gastrin release can be demonstrated by sham feeding, insulin-induced hypoglycemia, and administration of the vagal stimulant ψ -aminobutyric acid. In contrast to these stimulatory vagal effects, hypergastrinemia, observed after vagotomy, suggests that inhibitory vagal effects on gastrin release may also exist. Cholinergic neurons stimulate gastrin secretion directly by actions on gastrin cells. By decreasing somatostatin secretion, cholinergic neurons also indirectly stimulate gastrin release. Evidence suggests that vagal stimulation of gastrin release is mediated by bombesin or its mammalian equivalent, gastrin-releasing peptide, acting as a neurotransmitter in the gastric wall. Adrenergic stimulation has also been noted to increase gastrin release.

Chronic gastric infection with *Helicobacter pylori* causes increased acid secretion by altering gastrin release.^{4,5} *H. pylori* has been observed to upregulate proinflammatory cytokines, including interleukin (IL)-6, IL-8, and tumor necrosis factor- α (TNF- α). Several inflammatory mediators have been demonstrated to stimulate gastrin release from isolated gastrin cells. The putative gastrin secretagogues include IL-1, IL-8, TNF- α , interferon- ψ , and leukotrienes C4 and D4. The same factors that affect gastrin release also influence gastrin mRNA expression. Food ingestion increases gastrin mRNA abundance, whereas fasting and somatostatin decrease gastrin mRNA production. Chronic achlorhydria, as seen in pernicious anemia, increases gastrin mRNA production.

In addition to stimulating acid secretion from gastric parietal cells (detailed later in this chapter), gastrin has important physiologic actions in the control of gastrointestinal mucosal growth. The acid-secreting oxyntic mucosa is particularly sensitive to the trophic actions of gastrin, but the mucous membranes of the duodenum, colon, and pancreatic parenchyma are also affected. Stimulation of mucosal growth by gastrin is enhanced by the presence of solid food in the diet. The 17- and 34-amino-acid forms of gastrin are equipotent in stimulating mucosal growth. In humans, the relative importance of gastrin and other influences, such as the composition and form of the diet and the actions of other trophic hormones, have not been completely established. Prolonged stimulation by high levels of gastrin, as seen in the Zollinger-Ellison syndrome, is associated with hypertrophy of the gastric mucosa. Smaller increases in circulating gastrin, such as those that follow vagotomy, do not cause mucosal hypertrophy.

Somatostatin

Somatostatin, like gastrin, is very significant in gastric physiology. Somatostatin was first isolated from hypothalamic tissues and was named for its ability to inhibit the release of growth hormone. The peptide was subsequently localized in neurons in central and peripheral nervous systems, and in endocrine cells in the pancreas, stomach, and intestine. The wide tissue distribution of somatostatin suggested important regulatory functions, a concept validated by many investigations.

The human somatostatin gene is located on chromosome 3 and encodes for a precursor of 116 amino acids (Fig. 43.9). The somatostatin molecule is contained in the carboxyl-terminal sequence of this preprohormone. The first 24 amino acids of the amino terminus of preprosomatostatin constitute a signal peptide; cleavage of this signal peptide leaves prosomatostatin. Enzymatic cleavage of an additional 64-amino-acid segment from prosomatostatin forms somatostatin 28. Further processing of somatostatin 28 to somatostatin 14 is tissue-specifically regulated. In the stomach, most somatostatin exists as the shorter peptide.

Gastric somatostatin release responds to luminal, hormonal, and neural signals. Luminal acidification is associated with increased somatostatin release, whereas somatostatin release decreases when luminal pH is increased. A number of peptides have been demonstrated experimentally to release somatostatin from the stomach, including gastrin, cholecystokinin, and secretin. β -Adrenergic agonists have also been

shown to release somatostatin. In contrast, electrical stimulation of vagal nerves inhibits somatostatin release, as does the cholinergic agonist methacholine.

The most important gastric function of somatostatin appears to be regulation of acid secretion and gastrin release. Circulating somatostatin appears to be important in modulating gastric acid secretion; locally released somatostatin functions to regulate gastrin release. In each instance, somatostatin serves an inhibitory function, decreasing acid secretion and diminishing the release of gastrin. In animals, antral or duodenal acidification has been associated with an increase in circulating somatostatin. Increases in circulating somatostatin are followed, in turn, by decreased gastric acid secretion. Infusion of exogenous somatostatin in doses that produce somatostatin levels similar to those observed postprandially has also been shown to inhibit acid secretion. In humans, concentrations of somatostatin capable of inhibiting acid secretion can do so without altering serum gastrin levels, indicating a direct action on the acid-secreting fundic mucosa.

Somatostatin is believed to influence gastrin secretion through a locally active intramucosal mechanism. Local actions of somatostatin are supported by ultrastructural studies of antral somatostatin cells, which demonstrate long cytoplasmic processes that make intimate cell-to-cell contact with antral gastrin cells. The presence of somatostatin at these sites of cellular contact implies that somatostatin cells influence the function of gastrin cells through local release of the peptide. Somatostatin can also reach neighboring gastrin cells through diffusion or local blood flow. A number of experiments have suggested that release of somatostatin and gastrin is functionally, although reciprocally, linked. For example, in anesthetized animals, an increase in gastric pH or ingestion of a meal is associated with increases in gastrin and decreases in somatostatin in antral venous blood. Cholinergic agents stimulate gastrin release while inhibiting somatostatin release. Prostaglandin E_2 , in contrast, inhibits gastrin release and stimulates somatostatin secretion. These and similar observations suggest that increases in somatostatin release are often associated with decreased gastrin secretion. A family of five somatostatin receptors has been cloned. Inhibition of gastrin-stimulated gastric acid secretion is mediated by somatostatin receptor subtype 2.

Ghrelin

The control of feeding behavior and nutrient intake is an extremely important, and highly regulated, biologic process.

FIGURE 43.9. Derivation of somatostatin 14 from preprosomatostatin precursor.

The control of caloric intake is centered in the hypothalamus, which integrates information on nutritional status, environment, and energy expenditure. This process is regulated by both central and peripheral orexigenic and anorexigenic signals. Peripheral messengers include adiposity signals such as leptin, and a variety of gut peptides. The stomach has recently been recognized as the site of production of an important stimulant of feeding, ghrelin.

Ghrelin is a gastric peptide that is localized to oxyntic glands. Gastric ghrelin cells represent about one fourth of endocrine cells within the gastric mucosa. Ghrelin-expressing cells have no microscopic contact with the gastric lumen, and are presumed to sense signals relevant to feeding from the basolateral side. Ghrelin-positive cells are accordingly closely associated with capillaries in the lamina propria. The hormone is also produced in the hypothalamus.

The ghrelin receptor is a member of the family of G protein–coupled receptors and contains seven transmembrane domains. Ghrelin receptors are widely distributed among both central and peripheral tissues, including the pituitary gland, hypothalamus, pancreas, stomach, and intestine. Ghrelin causes growth hormone secretion following either peripheral or central administration, and release of growth hormone from cultured pituitary cells.

4 Ghrelin plays an important role in the control of food intake and energy metabolism.^{6,7} Ghrelin is the only orexigenic hormone identified to date. In humans, the intravenous

administration of ghrelin at physiologic concentrations induces the sensation of hunger and stimulates oral intake. Circulating ghrelin levels peak just prior to meal initiation and decline rapidly postprandially. Ghrelin secretion is increased by weight loss and by restriction of caloric intake. Serum ghrelin levels are increased in anorexic individuals and depressed in obese subjects.^{8,9} In animals, ghrelin administration has been found to stimulate food intake, to induce growth of adipose tissues, and to increase body weight. Administration of ghrelin antibody or ghrelin receptor antagonists blunts ghrelin-induced weight gain and positive energy balance.

Ghrelin is a circulating hormone with CNS effects. The arcuate nucleus of the hypothalamus is a crucial site for the integration of fasting and feeding signals.¹⁰ Two types of neurons, with opposing actions on feeding behavior, have been identified in the arcuate nucleus. Neurons that express proopiomelanocortin (POMC) and cocaine and amphetamine-related transcript (CART) suppress food intake, reduce body weight, and increase energy expenditure. In contrast, neurons producing neuropeptide Y and agouti gene–related transcript (AgRP) are orexigenic. These cells act to stimulate food intake and reduce energy expenditure. Ghrelin directly mediates the activities of these two types of neurons, as depicted in Figure 43.10. Direct peripheral effects of ghrelin on peripheral tissues that contribute to the regulation of body weight and energy homeostasis may also exist.

FIGURE 43.10. Source of hormones that act within the brain to regulate appetite and energy homeostasis. The arcuate nucleus of the hypothalamus (ARC) contains neurons that reciprocally influence ingestive behavior. Activation of NPY/AgRP neurons increases appetite and metabolism. Activation of POMC/CART neurons suppresses appetite and energy expenditure. The vagal nucleus of the tractus solitarius receives input from the hypothalamus as well as from the periphery via the vagus nerve.

GASTRIC ACID SECRETION

Cellular Events

5 An appreciation of the mechanisms that control gastric acid formation is essential to a discussion of gastric disease. An understanding of the cellular basis of acid secretion by the gastric parietal cell also provides a foundation for discussing the pharmacologic treatment of acid-peptic diseases. The basolateral membrane of the parietal cell contains specific receptors for histamine, gastrin, and acetylcholine, the three major stimulants of acid production.¹¹ Each stimulant reaches the parietal cell by a different route. Histamine is released from mast-like cells within the lamina propria and diffuses to the mucosa, acetylcholine is released in close proximity to the parietal cells from cholinergic nerve terminals, and gastrin is delivered by the systemic circulation to the fundic mucosa from its source in the antrum and proximal duodenum (Fig. 43.11), activating protein kinase A, which in turn catalyzes protein phosphorylation. The target protein molecules for this phosphorylation, in turn, stimulate acid production.

Acetylcholine and related cholinergic agonists activate parietal cells after binding to muscarinic receptors. The stimulatory effects of acetylcholine and its congeners can be abolished by atropine. The action of acetylcholine is mediated by muscarinic receptor subtype 3 (M_3). Studies suggest that cholinergic stimulation of parietal cell function is coupled to enhanced mobilization of intracellular calcium. The resultant transient increases in intracellular calcium activate mechanisms that stimulate acid secretion (Fig. 43.12). Evidence also indicates that occupation of acetylcholine receptors increases turnover of specific membrane phospholipids termed *phosphatidylinositides*. Acetylcholine–receptor binding is followed by activation of membrane-associated phospholipase C. Phospholipase C acts on phosphatidylinositol-4,5-bisphos-

phate (PIP_2) within the plasma membrane to liberate water-soluble inositol triphosphate (IP_3) and diacylglycerol. A major action of IP_3 is to increase intracellular calcium, mainly from intracellular stores in the endoplasmic reticulum. The resulting increased cytosolic calcium interacts with calmodulin or other calcium-binding proteins. Calmodulin kinase type II is involved in parietal cell activation by acetylcholine. Intracellular calcium in this form is postulated to modulate parietal cell function through protein phosphorylation or enzyme activation. Diacylglycerol, the second product released by hydrolysis of PIP_2 , activates a class of protein kinases that are phospholipid dependent and Ca^{2+} activated, protein kinase C. Protein kinase C in turn acts to phosphorylate a set of proteins that are distinct from those affected by the calmodulin-dependent system. The ultimate result of this protein phosphorylation is parietal cell activation and hydrogen ion secretion.

Parietal cells can also be activated by occupation of specific gastrin receptors. As with cholinergic stimulation, gastrin exposure increases membrane PIP_2 turnover (see Fig. 43.12). Like acetylcholine, the actions of gastrin depend highly on increases in intracellular calcium and activation of protein kinase C.

Although histamine, acetylcholine, and gastrin occupy separate receptors on the parietal cell and activate differing second-messenger systems, each secretagogue ultimately acts by means of a specialized ion transport system called the *parietal cell proton pump*. This membrane-bound protein is located in the secretory canaliculus of the parietal cell; the peptide has not been identified in other gastric cells or in significant amounts in other organs. The proton pump is an H^+K^+ -adenosine triphosphatase (ATPase) that electroneutrally exchanges cytosolic H^+ for luminal K^+ . Hydrogen ions are concentrated 2.5-million-fold within the secretory canaliculus, and the hydrolysis of ATP is the energy source for transport against the steep electrochemical gradient generated. For each H^+ ion transported to the luminal

FIGURE 43.11. Interactions of cell types that affect parietal cell acid secretion.

FIGURE 43.12. Cellular mechanisms controlling parietal cell acid secretion. surface of the canicular membrane, one K⁺ ion is transported to the cytosolic surface (Fig. 43.13). This cotransport requires that K⁺ be continuously supplied to the luminal surface of the secretory membrane. This requirement is satisfied by conductance of K⁺ across the canicular membrane from intracellular stores. Chloride ions also enter the secretory canaliculus by diffusion.

FIGURE 43.13. Gastric H⁺-K⁺-adenosine triphosphatase (ATPase). ADP, adenosine diphosphate; ATP, adenosine triphosphate; Pi, phosphate ion.

Activation of the H⁺-K⁺-ATPase significantly increases intracellular OH⁻ generation, with potential cellular toxicity. Carbonic anhydrase, which is associated with the canicular membrane, converts OH⁻ to HCO₃⁻. The HCO₃⁻ produced is disposed of by exchange for Cl⁻ at the basolateral membrane. Intracellular Cl⁻ thus acquired supplies the necessary Cl⁻ on a one-to-one basis for each H⁺ secreted. The transcellular exchange of H⁺ for HCO₃⁻ ensures that the voluminous secretion of hydrochloride at the luminal surface of the gastric mucosa is matched by an equivalent delivery of base to submucosal capillaries. Parietal cell ionic transport pathways are shown in Figure 43.14.

The function of the proton pump is highly regulated. In the unstimulated state, the enzyme is sequestered in cytoplasmic structures termed *tubulovesicles* that are not connected to the gastric lumen. Tubulovesicle membranes in this state have a low permeability to KCl. Stimulation of acid secretion causes tubulovesicles to fuse with apical secretory membranes and increases membrane permeability to KCl. In this way, the fusion of tubulovesicle membrane exposes the H⁺-K⁺ pump to the gastric lumen and simultaneously provides the K⁺ substrate necessary for acid secretion.

Parietal cells also contain membrane receptors that inhibit acid secretion. Specific receptors for somatostatin have been identified using isolated gastric cells. Activation of isolated parietal cells by histamine, pentagastrin, or the cholinergic agonist carbachol can be blocked by somatostatin 28. In the case of histamine activation, the inhibitory effects appear to be mediated by the ability of somatostatin to block the production

FIGURE 43.14. Ionic fluxes associated with acid secretion by the parietal cell.

of cyclic adenosine monophosphate (cAMP). Somatostatin appears to inhibit the actions of these agonists at a point distal to second-messenger generation. Gastric parietal cells also contain receptors for prostaglandins, notably prostaglandin E_2 and its derivatives. Prostaglandin E_2 is a potent inhibitor of histamine-stimulated parietal cell activation, probably by a mechanism that inhibits formation of cAMP. Prostaglandin inhibition is specific for histamine; the actions of gastrin or carbachol are not affected. Epidermal growth factor and transforming growth factor- α also inhibit histamine-stimulated acid secretion through effects on cAMP production.

These considerations of the cellular basis of acid production demonstrate how parietal cell function can be altered pharmacologically. Gastric acid production can be blocked by receptor antagonists for each of the three primary stimulants—gastrin, acetylcholine, and histamine. Direct inhibition of acid production can be effected by derivatives of somatostatin or prostaglandin E_2 . All forms of stimulated acid production can be blocked by agents that act as inhibitors of the parietal cell proton pump. Agents that act at each of these points have been developed, and their appropriate clinical applications are discussed in subsequent chapters.

Regulation of Acid Secretion

Given the multiple receptors on parietal cells, it is not surprising that a great deal of secretagogue interdependence, both stimulatory and inhibitory, exists in humans. Parietal cell activation, and the resultant acid secretion, is greater in response to a combination of agonists than it is in response to the total effect of agents used singly. This increase in responsiveness is defined as *potentiation*. Potentiating interactions are most apparent when agents are used that act by way of different second-messenger systems. Thus, histamine strongly potentiates the acid-secretory response to pentagastrin or to carbachol in humans. Conversely, blockade of receptors to one stimulant also decreases responsiveness to the other agonists. For example, blocking histamine receptors with agents such as cimetidine decreases responsiveness to pentagastrin, even though gastrin receptors are not directly affected. These inhibitory interactions are exploited therapeutically in the treatment of acid-peptic diseases.

Humans normally secrete 2 to 5 mEq/h of hydrochloride in the fasting state, constituting basal acid secretion. Both vagal tone and ambient histamine secretion are presumed to be important in determining the rate of basal acid secretion. In humans, truncal vagotomy decreases basal secretion by approximately 85%. Similarly, H_2 -receptor antagonists also inhibit basal acid secretion by approximately 80%. Gastrin does not have an important role in determining basal acid secretion in normal people.

Stimulated acid secretion begins with the thought, sight, or smell of food (Fig. 43.15). This cephalic phase of gastric acid secretion is mediated by the vagus nerve. Vagal discharge directs a cholinergic mechanism, and the cephalic phase of acid secretion can be inhibited by administering atropine. Vagal discharge secondary to cephalic stimulation also inhibits the release of somatostatin. Diminished secretion of somatostatin further augments stimulatory vagal effects, presumably by eliminating tonic inhibition of acid secretion exerted by somatostatin. The cephalic component of acid secretion can be measured in normal people by sham feeding and is approximately 10 mEq/h. The cephalic phase approximates 40% of the maximal acid-secretory response to gastrin infusion.

The gastric phase of acid secretion begins when food enters the stomach. The presence of partially hydrolyzed food constituents, gastric distention, and the buffering capacity of food all stimulate acid secretion. Gastrin is the most important mediator of the gastric phase of acid secretion. In normal humans, acid-secretory rates after a mixed meal average 15 to 25 mEq/h, approximately 75% of the maximal response achieved with infusion of exogenous gastrin or histamine. The meal response is less than the maximal response to exogenous stimulants because food also causes the release of somatostatin and initiates other inhibitory responses. In humans, 90% of meal-stimulated acid secretion is mediated by gastrin release.¹²

The inhibitory regulation of gastric acid secretion is accomplished by CNS, gastric, and intestinal mechanisms. Stimulated acid secretion can be inhibited experimentally by administering various neuropeptides into the lateral cerebral ventricles, including gastrin-releasing peptide (bombesin), corticotropin-releasing factor, and calcitonin gene-related peptide. Although the relevance of these observations to human physiology remains to be determined, it is likely that CNS inhibition of acid secretion exists in humans. In this regard, the vagus nerve has both a stimulatory and an inhibitory role in acid secretion and gastrin release. Vagotomy causes fasting and postprandial hypergastrinemia, indicating that an inhibitory regulation of gastrin release normally exists. Hypergastrinemia is sustained long term after vagotomy by hyperplasia of antral gastrin cells. The vagal fibers to the oxyntic region of the stomach appear to mediate this inhibitory effect.

In humans, the most important and clearly established gastric inhibitory influence is the suppression of gastrin release when the antral mucosa is exposed to acid. When luminal pH falls to 2.0, gastrin release stops. Antral acidification also suppresses the gastrin response to an ingested meal. Somatostatin acting locally in the gastric mucosa as a paracrine agent may mediate this important inhibitory response. Release of gastric somatostatin is reciprocally linked to that of gastrin; acidification of the antrum causes increases in somatostatin release and decreases in gastrin secretion. Antral distention also inhibits stimulated acid secretion.

The entry of digestive products into the intestine begins intestinal-phase inhibition of gastric acid secretion. Acidification of the duodenal bulb inhibits acid secretion, and although exogenous secretin also can inhibit acid secretion, this effect appears to be independent of the release of secretin from the duodenal mucosa. Hyperosmolar solutions and those containing fat also potentially inhibit acid secretion. Several peptides,

including secretin, somatostatin, peptide YY, gastric inhibitory peptide, and neurotensin, have been proposed as mediators of the intestinal phase effects.

PEPSIN

- 6** Pepsins are a heterogeneous group of proteolytic enzymes that are secreted by the gastric chief cells. Pepsin is derived under acidic conditions from pepsinogen by the autocatalytic loss of a variable amino-terminal sequence of the parent compound. This conversion occurs slowly at pH values of 5.0 to 6.0 and occurs rapidly when luminal pH approximates 2.0. Pepsin catalyzes the hydrolysis of a wide variety of peptide bonds that contain acidic residues, with a pH optimum for hydrolysis between 1.5 and 2.5. Once activated, pepsin is sensitive to ambient pH values; it is irreversibly denatured at pH 7.0 or greater.

The most important stimulus for pepsinogen secretion is cholinergic stimulation. Acetylcholine and its derivatives stimulate pepsinogen secretion by a mechanism that can be antagonized by atropine, indicating a muscarinic receptor. The receptor is an M_1 type. Endogenous cholinergic stimulation through the vagal nerve results in the formation of a gastric secretion that is rich in pepsin. Although both exogenous histamine and gastrin can stimulate pepsin secretion, their actions appear to be indirectly due to the concomitant secretion of gastric acid rather than to direct stimulation of chief cells. Chief cells have also been shown to possess cholecystokinin receptors, and cholecystokininlike peptides appear to have a direct stimulatory action on chief cells. The oxyntic mucosa contains somatostatin cells near chief cells. Pepsinogen secretion in response to a variety of stimuli has been demonstrated to be inhibited by somatostatin.

The major physiologic function of pepsin is to initiate protein digestion. Pepsin is highly active against collagen and may be important in the digestion of animal protein. Intragastric

protein hydrolysis by pepsin is incomplete, and relatively large peptides enter the intestine, although amino acids and small peptide fragments are released. These products of partial hydrolysis are important signals for gastrin and cholecystokinin release, which in turn regulate digestive processes. In this way, pepsin also contributes to the overall coordination of the digestive process.

INTRINSIC FACTOR

- 7** The gastric mucosa is the site of production of intrinsic factor, which is necessary for the absorption of cobalamin from the ileal mucosa. Total gastrectomy is regularly followed by cobalamin malabsorption, as is resection of the proximal stomach or atrophic gastritis that involves the oxyntic mucosa.

Autoradiographic and immunocytochemical techniques have confirmed the parietal cell as the site of intrinsic factor synthesis and storage in humans. Intrinsic factor secretion, like acid secretion, is stimulated by histamine, acetylcholine, and gastrin. Unlike acid production, intrinsic factor secretion peaks rapidly after stimulation and then returns to baseline. The amount of intrinsic factor secreted usually greatly exceeds the amount needed to bind and absorb available dietary cobalamin.

GASTRIC BICARBONATE PRODUCTION

It is generally agreed that the gastric mucosa secretes HCO_3^- in addition to acid. The cells responsible for HCO_3^- production are presumed to be the surface mucous cells facing the gastric lumen, and HCO_3^- transport has been postulated to protect against damage from luminal acid. In theory, H^+ ions diffusing from luminal bulk fluids toward the gastric mucosa could be neutralized by secreted HCO_3^- near the surface (Fig. 43.16).

FIGURE 43.16. Schematic representation of mucosal bicarbonate secretion showing neutralization of luminal hydrogen ions immediately above the mucosal surface.

In this way, nearly neutral pH can be maintained at the mucosal surface, even if the total amount of hydrochloride secreted greatly exceeds gastric HCO_3^- production. The occurrence of pH gradients at the surface of the gastric mucosa have been demonstrated in humans using microelectrodes. Drugs or chemicals that inhibit bicarbonate secretion result in acidification of the mucosal surface.

The degree of luminal acidity, reflected by pH, required to stimulate bicarbonate secretion is greater in the stomach than in the duodenum. Direct exposure of the gastric mucosa to pH levels of 2.0 or more increases bicarbonate secretion. In the duodenum, exposure of the mucosa to pH 5.0 doubles bicarbonate secretion, whereas exposure to pH 2.0 increases alkaline secretion 10-fold.

Cholinergic agonists, vagal nerve stimulation, and sham feeding have all been shown to increase gastric HCO_3^- production. The effects of cholinergic stimulation can be blocked by atropine. In the human stomach, exposure to luminal perfusates at pH 2.0 has been associated with increased release of prostaglandin E_2 . Prostaglandin E_2 and its synthetic derivatives are also potent stimulants of gastric bicarbonate secretion. Because mucosal bicarbonate production can be decreased in experimental models by indomethacin, endogenous prostaglandins are thought to be important in the mucosal alkaline response.

GASTRIC BLOOD FLOW

Because the gastric mucosa is metabolically highly active, control of mucosal blood flow is of great physiologic importance. In addition, studies have implicated perfusion abnormalities in the development of mucosal lesions during periods of stress. Mucosal blood flow is regulated by neural, hormonal, and locally active influences.

Postganglionic sympathetic nerve fibers reach the stomach in association with its blood supply and richly innervate small mucosal arteries. Mucosal capillaries do not receive adrenergic innervation. Electrical stimulation of sympathetic nerves supplying the stomach is followed by decreased total gastric blood flow, decreased flow in celiac and gastropiploic vessels, and diminished blood flow to the mucosa. Studies in animals demonstrate that vasoconstriction of the gastric vascular bed is mediated by α -adrenergic receptors and that vasodilation is mediated by β -adrenergic receptors.

Stimulation of the vagus nerve is followed by a prompt increase in blood flow, suggesting a dilatory effect of parasympathetic nerves. The effects of vagal stimulation on mucosal blood flow are complicated by accompanying increases in acid

secretion. Almost all stimuli that increase acid production also increase blood flow secondarily.

A number of gastrointestinal peptide hormones affect gastric blood flow, most because of their ability to increase or decrease acid secretion. Thus, gastrin, because it is a potent stimulant of acid secretion, also increases mucosal blood flow. Cholecystokinin appears to have direct vasodilatory effects on the gastric vasculature. Vasopressin has been well demonstrated to have direct vasoconstrictor activity.

Nitric oxide modulates basal gastric vascular tone and controls gastric vasodilation and hyperemia. Nitric oxide mediates the hyperemic response that accompanies increases in acid secretion, although the molecule has no direct stimulatory role in acid production.

Prostaglandins are important mucosally produced compounds that have clear effects on the gastric vasculature. Prostaglandins of the E class have been shown in animals and humans to increase gastric blood flow at doses that decrease acid secretion. Indomethacin, in doses sufficient to inhibit prostaglandin formation, decreases the diameter of submucosal blood vessels and reduces basal blood flow. Complete inhibition of cyclooxygenase activity causes an approximate 50% reduction in resting blood flow. These studies suggest that endogenous, locally produced prostaglandins are crucial to maintaining basal gastric blood flow in humans and probably act in concert with endogenous nitric oxide.

GASTRIC MOTILITY

Gastric Smooth Muscle

Consideration of gastric motility requires that the stomach be viewed in functional terms as two different regions, the proximal one third and the distal two thirds. These areas are distinct in terms of smooth muscle anatomy, electrical activity, and contractile function. The regions do not correspond to the traditional anatomic divisions of fundus, corpus, and antrum.

In the proximal stomach, three layers of gastric smooth muscle can be distinguished: an outer longitudinal layer, a middle circular layer, and an inner oblique layer. In the distal two thirds of the stomach, the longitudinal layer is most clearly defined, and the inner oblique layer is usually not distinct. The gastric smooth muscle ends at the pylorus.

The smooth muscle of the proximal stomach is electrically stable, whereas the smooth muscle of the distal stomach demonstrates spontaneous, repeated electrical discharges. Gastric smooth muscle exhibits myoelectric activity that is based on a highly regular pattern called the *slow wave*.¹³ In the

stomach, slow waves occur with a frequency of three cycles per minute. Slow waves do not, by themselves, lead to gastric contractions, but they do set the maximum rate of contractions at three per minute. Gastric contractions occur when action potentials are phase locked with the crest of the slow wave.

Extracellular electrical recording from the serosal surface of the stomach also demonstrates the intrinsic electrical activity of the distal stomach in the form of pacesetter potentials. Pacesetter potentials reflect partial depolarization of the gastric smooth muscle cell and are recorded during relatively long periods (2 or 3 seconds). Pacesetters originate along the greater curvature at a point in the proximal third of the stomach. Pacesetter potentials, discharging at a rate of three times per minute in humans, drive cells located distally. Spread of the pacesetter potentials is faster along the greater curvature, so that a ring of electrical activity reaches the pylorus simultaneously along both curvatures. The pacesetter potentials do not result in smooth muscle contraction unless an additional depolarization is superimposed in the form of an action potential. When action potentials occur, a ring of smooth muscle contraction moves peristaltically along the distal stomach toward the pylorus.

Duodenal slow-wave frequency and maximum rate of phasic contractions are higher than those observed in the stomach. The duodenal rate is approximately 12 cycles per minute; the contraction rate declines progressively to nine cycles per minute in the distal ileum.

The smooth muscle activity of the proximal stomach is fundamentally different from that of the distal stomach. There are no pacesetter or action potentials in the proximal stomach. As a result, peristalsis does not occur. Proximal gastric contraction is tonic and prolonged, and increases in luminal pressure are often sustained for several minutes.

Coordination of Contraction

Important vagally mediated reflexes influence intragastric pressure, presumably by affecting contractile activity of smooth muscle in the proximal stomach. The most important reflex is termed *receptive relaxation* and occurs with ingestion of a meal. Increasing gastric volumes are accommodated with little increase in intragastric pressure by relaxation of the proximal stomach. This receptive relaxation allows the proximal stomach to act as a storage site for ingested food in the immediate postprandial period. Afferent impulses, presumed to originate from stretch receptors in the gastric wall, are carried along vagal fibers; efferent vagal discharges are inhibitory. Receptive gastric accommodation is lost after either truncal or proximal gastric vagotomy. After the meal has been ingested, proximal contractile activity increases; alterations in proximal gastric tone cause the compressive movement of gastric content from the fundus to the antrum.

Food that enters the antrum from the proximal stomach is propelled peristaltically toward the pylorus. A number of observations indicate that the pylorus closes 2 or 3 seconds before the arrival of the antral contraction ring. This coordinate closing of the pylorus allows a small bolus of liquid and suspended food particles to pass while repulsing the main mass of gastric contents back into the proximal antrum. The

churning action that results mixes ingested food particles, gastric acid, and pepsin, and contributes to the grinding function of the stomach. Solid food particles do not ordinarily pass the pylorus unless they are no larger than 1 mm.

A consistent finding in humans ingesting a mixed solid-liquid meal is that liquids empty more quickly than solids. Characteristically, solid food empties only after a lag period, whereas liquid emptying begins almost immediately. A traditional interpretation of these human observations has been that the proximal stomach is the dominant force in determining how quickly a liquid meal empties by the gastroduodenal pressure gradient generated by proximal gastric contractions. The actions of the proximal stomach in liquid emptying are also regulated by the sieving actions of the antropyloric segment and are modified by the nutrient composition of the ingested meal. The distal gastric segment has been postulated to control solid emptying through its grinding and peristaltic actions. This traditional concept of the two-component stomach is useful in considering observations in patients who have undergone gastric operative procedures. Patients who have undergone proximal gastric vagotomy exhibit accelerated emptying of liquids but have normal solid emptying. Because of loss of receptive relaxation, the denervation of the proximal stomach is presumed to increase intragastric pressure and accelerate liquid emptying while leaving the distal gastric segment unaffected. Conversely, vagal denervation of the antrum interrupts gastric emptying of solids to a greater degree than liquids. Although this model of gastric emptying oversimplifies the many mechanisms (gastric, pyloric, and intestinal) that work in concert to control gastric emptying, it provides a useful framework for considering the effects of gastric surgical procedures.

CHAPTER 44 ■ GASTRODUODENAL ULCERATION

MICHAEL W. MULHOLLAND

KEY POINTS

- 1 Mucosal infection with *Helicobacter pylori* is the factor that contributes to ulcer pathogenesis in most patients.
- 2 *H. pylori* virulence factors include vacuolating cytotoxin A (VacA) and cytotoxin-associated gene A (CagA).
- 3 As a group, patients with duodenal ulcers have an increased capacity for gastric acid secretion relative to normal people.
- 4 Current treatment of peptic ulceration involves a combination of an antisecretory drug, usually a proton pump inhibitor, with antibiotics.
- 5 Hemorrhage is the leading cause of death associated with peptic ulcer. Patients with recurrent hemorrhage and elderly patients are at greatest risk of death.
- 6 For perforation, current therapy includes omental patch closure with postoperative anti-*H. pylori* therapy. Minimally invasive approaches are becoming standard practice.
- 7 Major trauma accompanied by shock, sepsis, respiratory failure, hemorrhage, or multiorgan injury is often accompanied by acute stress gastritis.

EPIDEMIOLOGY

Peptic ulceration remains a major public health problem worldwide. Some 300,000 new cases of peptic ulcer are diagnosed in the United States each year, and 4 million people receive some form of ulcer treatment. In the United States, ulcer mortality and hospitalization rates have fallen since the early 1980s, but physicians are now treating a cohort of older patients with frequent comorbidity and ulcer disease of greater chronicity. Mortality attributed to peptic ulceration remains substantial; ulcer disease is listed as a contributing cause of death in more than 10,000 cases annually.

The surgical treatment of peptic ulcer has changed fundamentally. New insights into disease pathogenesis, especially the realization that gastric infection has a role in most cases of peptic ulceration, have been especially exciting. Antibiotics are now front-line antiulcer therapy. A number of powerful antisecretory drugs have been introduced into clinical practice. Medical, endoscopic, and surgical therapies are frequently integrated in the care of individual patients.

No clear racial predilection for the development of duodenal ulceration exists, but genetic factors can be important. Hyperpepsinogenemia I, with autosomal dominant inheritance, is common in duodenal ulcer, although the relation of this trait to the development of ulceration remains obscure. A number of rare familial syndromes associated with peptic ulceration have been described.

PATHOPHYSIOLOGY

The pathogenesis of peptic ulceration is complex and multifactorial but increasingly understood. Approximately 85% of peptic ulcer cases are caused by *Helicobacter pylori*, with almost all other cases due to use of nonsteroidal anti-inflammatory drugs (NSAIDs).¹ The development of peptic ulceration is often depicted as a balance between chronic inflammatory injury, acid-peptic secretion, and mucosal defense, with the equilibrium shifted toward disease. Although acid-peptic secretion is crucial in the development of ulcers, usually a defect in mucosal defense induced by bacterial infection also exists to tip the balance away from health. Mucosal infection with *H. pylori* is the factor that contributes to ulcer pathogenesis in most patients.

Helicobacter pylori

The relation between *H. pylori* infection and ulceration is inferential but overwhelmingly strong; a causal relation between *H. pylori* infection and peptic ulceration has not been tested directly. Because *H. pylori* infection is difficult to eradicate with certainty, and because of the potentially serious consequences of infection, the intentional exposure of humans to the organism to establish such a relation is not justified.

Many lines of evidence establish *H. pylori* as a factor in the pathogenesis of duodenal ulceration:

- *H. pylori* is the primary cause of chronic active gastritis, characterized by nonerosive inflammation of the gastric mucosa. Antral gastritis is nearly always present histologically in patients with duodenal ulcer, and *H. pylori* can be isolated from gastric mucosa in almost all cases.
- Gastric metaplasia is extremely common in duodenal epithelium surrounding areas of ulceration. *H. pylori* binds only to gastric-type epithelium, regardless of location; metaplastic gastric epithelium can become colonized by *H. pylori* from gastric sources. Gastric metaplasia of the duodenal bulb is a nonspecific response to damage and is the means by which antral gastritis with *H. pylori* is converted to active chronic duodenitis.
- Eradication of *H. pylori* with antimicrobials that have no effect on acid secretion leads to ulcer healing rates superior to those seen with acid-suppressing agents.
- Relapse of duodenal ulcer after antimicrobial therapy is preceded by reinfection of the gastric mucosa by *H. pylori*.

In addition, half of patients evaluated for dyspepsia, but without ulceration, have histologic evidence of mucosal bacterial infection. Furthermore, 20% of healthy volunteers harbor the bacteria; the incidence of bacterial carriage in the healthy, asymptomatic population increases with age. The occurrence of peptic ulcers in only a small proportion of people who carry the organism suggests that other factors must also act to induce ulceration. The ability of *H. pylori* infection to induce alterations in gastric acid secretion is a prerequisite for ulcer development in most patients.

H. pylori is the most common bacterial infection worldwide. *H. pylori* infection is usually acquired in childhood and lasts lifelong absent specific therapy. Epidemiologic studies

suggest that *H. pylori* infection occurs via person-to-person contact, usually among family members. Transmission is believed to occur during a bout of gastroenteritis; the highest risk is associated with vomiting.

H. pylori is the only human bacterium to persistently infect the stomach.² The organism is actually somewhat fragile, being killed by exposure to high levels of oxygen and to the low pH found in the acidic lumen of the stomach. To avoid the bactericidal activity of the stomach, the organism has evolved mechanisms to move within the gastric environment, to adhere to gastric mucosa, and to protect itself from the harmful effects of acid. Over 300 genes of *H. pylori* are regulated by acid.

H. pylori bacteria are spiral shaped with polar flagella. Most bacilli are free-swimming within the mucous layer covering the gastric epithelium. The organisms orient according to a pH gradient, moving away from the lower pH of the lumen toward the epithelium. The majority of organisms remain motile within the mucous layer, but contact promotes adherence to epithelial cells, particularly in the region of intercellular junctions. The products of more than 30 genes are expressed on the outer membrane of the bacterium and function as adhesins to promote attachment to the gastric cells' surface. The best-characterized adhesin binds to the Lewis blood group antigen b. Adhesion triggers the expression of other bacterial genes, including bacterial virulence factors.

2 All strains of *H. pylori* cause persistent infection and all strains induce gastric inflammation. Yet, only 15% of infected individuals develop peptic ulceration and only 1% develop gastric adenocarcinoma. Differential expression of bacterial virulence factors is presumed to account for these observations. Two virulence factors are best characterized: vacuolating cytotoxin A (VacA) and cytotoxin-associated gene A (CagA)³ (Table 44.1).

VacA is a pore-forming cytotoxin. VacA is expressed in all strains of *H. pylori* but is polymorphic with marked variation in two regions. The VacA protein is 88 kD. Upon secretion from the bacterium, the protein moves to the host cell membrane, where it forms a ring structure in the shape of a flower.⁴ This ring complex inserts into the membrane of the host cell, creating a pore. VacA pores are permeable to anions and small neutral molecules, including urea. Pore formation may be a mechanism by which the organism obtains nutrients from gastric epithelial cells.

VacA also inserts into endosomal membranes, leading to osmotic swelling. VacA induces gastric cell death through apoptosis. This action is thought to occur via pore formation in mitochondrial membranes. VacA has been reported to interfere with immune T-cell activation and proliferation. This activity may inhibit clearance of the organism by immune mechanisms.

The second major virulence factor in *H. pylori* is termed CagA. The CagA gene is part of a region of DNA that is inserted into the genome of more virulent strains of *H. pylori*, termed a *pathogenicity island*.⁵ The genes in this island that are adjacent to the CagA gene encode proteins, which function as microscopic needles for the transfer of bacterial products into host gastric cells. CagA is transferred to host cells through this injection mechanism.

After CagA protein is transferred to host cells, it becomes phosphorylated on tyrosine residues by host cell kinases. Phosphorylated CagA activates a number of cellular signaling pathways involved in cellular polarity, cytoskeletal protein function, and cellular proliferation and differentiation. As a consequence, infected gastric cells change shape and become more elongated. Apical junctions between cells become disrupted, gaps develop between epithelial cells, and epithelial barrier function is lost. CagA protein also stimulates transcription factors involved in regulation of cellular proliferation. Disturbance of cellular function in favor of apoptosis affects epithelia restitution and may inhibit ulcer healing.

Acid-secretory Status

3 The formation of duodenal ulcers depends on gastric secretion of acid and pepsin. As a group, patients with duodenal ulcers have an increased capacity for gastric acid secretion relative to normal people (Table 44.2). The maximal acid output of normal men is approximately 20 mEq/h in response to intravenous histamine stimulation, whereas patients with duodenal ulcer secrete an average of approximately 40 mEq/h. Considerable overlap exists between these two groups, and the values for most people with duodenal ulcer fall within the normal range. The increase in acid secretion in some patients with duodenal ulcer has been postulated to be due to an increase in the mass of parietal cells in the acid-secreting

TABLE 44.1

HELICOBACTER PYLORI VIRULENCE FACTORS

Vacuolating cytotoxin A (VacA)
Forms ring structure in the shape of a flower
Inserts into gastric cell membrane, forming pore
Inserts into endosomal membranes, causing cellular swelling
Damages mitochondrial membranes
Causes leakage of ions and small molecules
Cytotoxin-associated gene A (CagA)
Contained within pathogenicity island DNA sequence
Injected into host cells
Phosphorylated by cellular oncogenes
Activates growth factor receptor–like signaling
Disturbs normal proliferation, adhesion, cytoskeletal function
Disturbs intercellular junctions, causing disruption of epithelial permeability
Elicits inflammatory response

TABLE 44.2

ETIOLOGY

PATHOGENESIS OF PEPTIC ULCER

Helicobacter pylori infection

ENDOCRINE CONSEQUENCES

- Increased basal serum gastrin
- Increased gastrin response to a meal
- Increased responsiveness to gastrin-releasing peptide
- Production of N^α-methylhistamine
- Decreased density of somatostatin cells
- Decreased mucosal somatostatin content

GASTRIC ACID SECRETION

- Increased acid = secretory capacity
- Increased basal secretion
- Increased pentagastrin-stimulated output
- Increased meal response
- Abnormal gastric emptying

MUCOSAL DEFENSE

- Decreased duodenal bicarbonate production
- Decreased gastric mucosal prostaglandin production
- Increased apoptosis of epithelial cells
- Disruption of epithelial barrier function
- Inhibited epithelial restitution

gastric mucosa or to an increased sensitivity to circulating gastrin.

Groups of patients with duodenal ulcer demonstrate a prolonged and larger acid-secretory response to a mixed meal than do groups of normal subjects. As with histamine-stimulated acid output, overlap exists between patients with duodenal ulcer and normal subjects. Disturbances in gastric motility can exacerbate meal-stimulated acid-secretory abnormalities.

Patients with duodenal ulcer have accelerated emptying of gastric contents, particularly liquids, after a meal, and duodenal acidification fails to slow emptying appropriately. In such patients, the duodenal mucosa can be exposed to low pH for prolonged periods relative to normal subjects.

Groups of patients with duodenal ulcer also demonstrate increased basal secretion of acid. Increased basal secretion can be demonstrated by nocturnal collection of gastric secretions.

Studies indicate that most of these secretory abnormalities are a direct consequence of *H. pylori* infection. Ironically, the earliest stages of *H. pylori* infection are accompanied by a marked decrease in gastric acid secretion. Acute antral gastritis is followed by fundal inflammation. Fundal inflammation is associated with mucosal production of a number of cytokines, including interleukin (IL)-1 β , IL-6, IL-8, and tumor necrosis factor- α (TNF- α). IL-1 β is a potent inhibitor of gastric acid secretion. Investigators have postulated that acute reduction in gastric acid secretion facilitates further gastric colonization with *H. pylori*. Acute hypochlorhydria resolves despite persistence of *H. pylori* and is followed by a state of chronically increased acid secretion.

Basal and peak acid outputs are increased in patients with duodenal ulcer infected with *H. pylori* relative to uninfected healthy volunteers. With eradication of *H. pylori* infection, basal acid output returns to normal within 4 weeks, and peak acid output declines to the normal range by 6 months. Peak acid output reflects parietal cell mass; the slow return to normal levels suggests that *H. pylori* infection may stimulate increases in the parietal cell mass.

Abnormalities in acid secretion and parietal cell mass appear to be due to *H. pylori*-induced hypergastrinemia.⁶ *H. pylori*-infected patients have increased basal serum gastrin levels, increased gastrin responses to meal stimulation, and an augmented gastrin response to intravenous gastrin-releasing peptide. Eradication of *H. pylori* infection causes serum gastrin levels to return to baseline. Gastric mucosal inflammatory cells and epithelial cells are activated by *H. pylori* infection to release cytokines such as IL-8, interferon- γ , and TNF- α . These cytokines are stimulants of gastrin release from cultured canine gastrin cells.

H. pylori expresses N^α-histamine methyltransferase activity. This enzyme produces N^α-methylhistamine, an abnormal analogue of histamine that can act as a gastric acid-secretory stimulant.

The concentration of somatostatin in the antral mucosa and the number of somatostatin-producing cells in the antrum are diminished in *H. pylori*-infected patients. Treatment of *H. pylori* infection is followed by increases in numbers of somatostatin cells and in mucosal somatostatin messenger RNA levels. These observations suggest that alterations in mucosal somatostatin metabolism may also contribute to the hypergastrinemia seen in *H. pylori*-infected patients by removing the inhibitory effects that somatostatin exerts on gastrin release. Somatostatin release is also suppressed by N^α-methylhistamine.

that abnormalities of mucosal defense might result in ulceration. In addition, several agents that are useful in the treatment of peptic ulceration are cytoprotective, which is defined as the ability to protect the mucosa from injury at doses lower than the threshold dose needed to inhibit acid secretion. The ability of cytoprotective agents to heal ulcers has suggested that abnormalities in mucosal defense are responsible for some instances of ulceration. Most investigative efforts have focused on the role of mucosally secreted bicarbonate and on mucosal prostaglandin production.

Gastric surface epithelial cells secrete mucus and bicarbonate, creating a pH gradient within the mucous layer that is nearly neutral at the mucous cell surface, even when the lumen is highly acidic. Failure of normal bicarbonate secretion locally would, in theory, result in exposure of surface epithelial cells to the peptic activity of gastric secretions at low pH. Patients with duodenal ulcers have been demonstrated to have significantly lower basal bicarbonate secretion in the proximal duodenum than normal subjects. In addition, in response to a physiologically relevant amount of hydrochloric acid instilled into the duodenal bulb, stimulated bicarbonate output was approximately 40% of the normal response. Abnormalities in duodenal bicarbonate secretion normalize after elimination of *H. pylori* in infected patients. These results suggest one mechanism by which ulceration could occur, even in patients secreting normal amounts of acid.

Diminished mucosal prostaglandin production has also been proposed to exist in subsets of patients with duodenal ulcer. Prostaglandins and prostaglandin analogues have been shown to exert cytoprotective effects, to accelerate healing of established duodenal ulcers, and to decrease acid secretion. In the duodenum, locally produced prostaglandins stimulate mucosal bicarbonate secretion. In patients with active duodenal ulceration, gastric mucosal production of prostaglandin E₂ and other prostanoids has been shown to be diminished. An increase in prostanoid synthesis within the gastric mucosa characterizes ulcer healing. Duodenal bicarbonate responses to prostaglandin E₂ are impaired in patients with duodenal ulcer.

Inflammatory responses to *H. pylori* infection are central to the pathogenesis of peptic ulceration. While *H. pylori* infection always induces inflammation, the patterns of response are not uniform. Three major patterns have been recognized.⁷ The most common pattern is a mild to moderate inflammation of all regions of the stomach. This form is not associated with major alterations in gastric acidity and most individuals are asymptomatic and do not develop peptic ulceration. Approximately 15% of infected individuals develop an antral-predominant form of gastritis. These individuals exhibit an intense inflammation limited to the antrum without involvement of the mucosa of the gastric corpus. Gastrin levels are elevated and acid secretion is high. Inhibitory control of gastric acid production is impaired in this form of gastritis. As a result, duodenal and prepyloric ulcers are common. The third form of inflammatory response, occurring in 1% of infected individuals, is least common but most serious. This form is characterized by corpus-predominant gastritis, hypochlorhydria, and gastric atrophy. This form of inflammatory response is considered a precursor state for gastric cancer. Individuals with the third pattern of inflammation demonstrate hypergastrinemia, low acid secretion, and diminished secretion of pepsinogen.

Mucosal Defense against Peptic Injury

Investigative attention has also focused on the ability of the duodenal mucosa to resist the injurious effects of luminal acid and pepsin. Because many patients with duodenal ulcer secrete normal amounts of acid and pepsin, it is attractive to postulate

Environmental Factors

Substantial evidence implicates cigarette smoking as an additive risk factor in the development of duodenal ulcers. Cigarette smoking impairs ulcer healing and increases the recurrence of ulcers. Continued smoking attenuates the effectiveness of active ulcer therapy. Cigarette smoking increases both the

probability that surgery will be required and the risks of operative therapy. Cessation of smoking is a key element of antiulcer therapy.

NSAIDs have emerged as a significant risk factor for the development of acute ulceration.⁸ Although acute mucosal injury caused by NSAIDs is more common in the stomach than in the duodenum, NSAID-induced ulcer complications occur with equal frequency in these two sites. NSAIDs produce a variety of lesions, ranging from hemorrhage, to superficial mucosal erosions, to deeper ulcerations. In the duodenum, it appears likely that invasive NSAID-associated ulcers result from underlying peptic ulcer diathesis compounded by the direct injurious effects of these drugs.

The ulcerogenic actions of NSAIDs have been attributed to their systemic suppression of prostaglandin production. Numerous experimental models have demonstrated the ability of NSAIDs to injure the gastroduodenal mucosa. Ulcers resembling those caused by NSAIDs can be produced experimentally by antibodies to prostaglandins. Conversely, NSAID-associated gastric ulcers can be prevented by the coadministration of prostaglandin analogues. Ulcers associated with NSAIDs usually heal rapidly when the drug is withdrawn, corresponding to the reversal of antiprostaglandin effects. All available NSAIDs appear to pose the hazard of gastroduodenal ulceration. Clinically important ulceration (of both the stomach and duodenum) is estimated by the U.S. Food and Drug Administration to occur at a rate of 2% to 4% per patient-year. The risks inherent with NSAID use appear to be increased by a history of *H. pylori* infection, by cigarette smoking, and by alcohol use. The incidence of NSAID-caused ulcer complications is highest in older patients, as is the attendant mortality rate. Peptic ulcer disease is rare in individuals who are *H. pylori* negative and who are not receiving NSAID medications.

A role of NSAIDs in upper gastrointestinal (GI) hemorrhage is widely recognized. The risk of bleeding is particularly acute for peptic ulceration. In three reports, spanning two decades, NSAIDs were linked to 50% to 75% of bleeding peptic ulcers, one third of deaths due to hemorrhage, and 30% of hospitalizations.⁸⁻¹⁰ Use of NSAIDs increases the risk of bleeding from peptic ulcer threefold for those under 65 years of age, but by eightfold for individuals over 75 years of age. The odds ratio for bleeding is 13 for patients with a prior history of bleeding ulcer.

Because of the risk of gastrointestinal side effects, a selective class of cyclooxygenase-2 (COX-2) inhibitors was developed for long-term pain relief and anti-inflammatory therapy. Selective COX-2 inhibitors have reduced potential to injure the gastrointestinal mucosa relative to standard NSAIDs.¹¹ The incidence of upper GI bleeding for celecoxib or rofecoxib therapy was reported to be fourfold less than standard NSAID therapy. Nonetheless, a definite risk for upper GI hemorrhage is still present, and is higher in aged patients. Concurrent use of aspirin with COX-2 inhibitors significantly undermines the safety advantages of the COX-2 agents, as does smoking. An increased incidence of adverse cardiovascular events caused the withdrawal of rofecoxib and valdecoxib from the market.

DIAGNOSIS

The cardinal feature of duodenal ulceration is epigastric pain. The pain is usually confined to the upper abdomen and is described as burning, stabbing, or gnawing. Unless perforation or penetration into the head of the pancreas has occurred, referral of pain is not common. Many patients report pain on arising in the morning. Ingestion of food or antacids usually provides prompt relief. In uncomplicated cases, abnormal physical findings are minimal. The differential diagnosis is broad and includes a variety of diseases originating in the upper gastrointestinal tract. The most common disorders to be

distinguished include nonulcerative dyspepsia, gastric neoplasia, cholelithiasis and related diseases of the biliary system, and both inflammatory and neoplastic disorders of the pancreas. In dyspeptic patients, the principal diagnoses that must be differentiated definitively are peptic ulceration and gastric cancer.

The evaluation of patients with suspected peptic ulceration usually involves endoscopy, the standard against which other diagnostic modalities are measured. Endoscopy is employed because it permits biopsy of the esophagus, stomach, and duodenum. Endoscopy must be recommended with discretion because of associated morbidity (approximately 1 per 5,000 cases) and higher costs.

Duodenal ulcer is characterized by lesions that are erosive to the bowel wall. When viewed endoscopically, the ulcers have a typical appearance. The edges are usually sharply demarcated and the underlying submucosa is exposed. The ulcer base is often clean and smooth, although acute ulcers and those with recent hemorrhage can demonstrate eschar or adherent exudate. Surrounding mucosal inflammation is common. The most frequent site for peptic ulceration is the first portion of the duodenum, with the second portion less commonly involved. Ulceration of the third or fourth portions of the duodenum is unusual, and occurrence in these sites should arouse suspicion of an underlying gastrinoma. Ulceration in the pyloric channel or the prepyloric area is similar in endoscopic appearance to duodenal ulceration, and ulcers in these areas demonstrate other clinical features similar to duodenal ulcers. Endoscopic demonstration of a duodenal ulcer should prompt mucosal biopsy of the gastric antrum to demonstrate the presence of *H. pylori* and guide subsequent therapy.

The hallmarks of the histologic appearance of duodenal ulcers are chronicity and invasiveness. Chronic injury is suggested by surrounding fibrosis; collagen is deposited in the submucosa during each round of ulcer relapse and healing. The adjacent mucosa often demonstrates evidence of chronic injury with infiltration of acute and chronic inflammatory cells. Gastric metaplasia, in which the duodenum exhibits histologic features of gastric mucosa, is common in the surrounding nonulcerated mucosa. The ulcer can extend for a variable distance through the wall of the duodenum, including the full thickness of the bowel in cases of perforation.

DRUG TREATMENT OF ULCER DISEASE

In the absence of active treatment, *H. pylori* infection is lifelong. Spontaneous healing of infected mucosa is very rare, occurring in less than 0.5% per patient-year. Current treatment of peptic ulceration involves a combination of an antisecretory drug, usually a proton pump inhibitor, with antibiotics.¹² This therapy is rational for most patients who are *H. pylori* positive and results in a high rate of sustained ulcer healing.

A large number of drug regimens have been described, but the most widely used treatment protocols combine a proton pump inhibitor, usually omeprazole, with two antibiotics, usually clarithromycin and metronidazole or amoxicillin. A combination of antibiotics is more effective than one antibiotic alone in almost all series. This triple therapy is administered for 7 or 14 days. Triple-drug therapy is cost effective and associated with a low rate of side effects, low rates of antibiotic resistance, and acceptable levels of patient compliance. *H. pylori* eradication rates of greater than 90% have been reported.

After elimination of *H. pylori*, ulcer recurrence rates reflect the rate of reinfection. In developed countries, reinfection rates of less than 10% at 5 years have been reported. Eradication of

H. pylori improves quality of life, as measured by symptoms, drug prescriptions, physician visits, and days of missed employment. To date, antibiotic resistance has been low, approximately 5% worldwide, but it is likely to increase with ongoing use of macrolide antibiotics.

HISTAMINE-RECEPTOR ANTAGONISTS

Histamine, released into the interstitial fluid by cells in the fundic mucosa, diffuses to the mucosal parietal cell. Histamine stimulates acid production by occupying a membrane-bound receptor and activating parietal cell adenylate cyclase. Histamine is released in response to a number of physiologic stimuli; blockade of histamine receptors inhibits most forms of stimulated acid secretion in humans. Parietal cell histamine receptors are classified as H_2 receptors because they are activated by agonists such as 4-methylhistamine and are selectively blocked by agents such as cimetidine. Some H_2 receptor antagonists also possess nongastric actions by binding to androgen receptors, by interacting with the hepatic microsomal oxidase system, and by crossing the blood-brain barrier. All clinically useful gastric histamine receptor antagonists are of the H_2 type.

H_2 -receptor antagonists bind competitively to parietal cell H_2 receptors to produce a reversible inhibition of acid secretion. An enormous worldwide experience has accumulated with the use of H_2 -receptor antagonists. The agents are effective and safe when used in the treatment of peptic ulcer. The various compounds have similar efficacy in terms of ulcer healing when used in doses that produce similar reductions in acid output. It is clear that H_2 -receptor blockers do not affect the underlying ulcer diathesis; if H_2 -receptor antagonists are stopped, recurrent ulceration occurs in more than half of patients within 1 year. The current understanding of the role of *H. pylori* in ulcer pathogenesis has changed the role of H_2 -receptor antagonists from primary therapy to that of a substitute for proton pump inhibitors in conjunction with antibiotic treatment.

PROTON PUMP BLOCKERS

Acid secretion by the gastric parietal cells is due to the active transport of hydrogen ions from the parietal cell cytoplasm into the secretory canaliculus in exchange for potassium. Because this so-called *proton pump* is tissue specific, being present only in gastric mucosa, its blockade would be expected to have minimal effects on nongastric functions. Omeprazole is representative of a family of compounds that selectively block the parietal cell proton pump.

Omeprazole is a weak base, with a pKa of approximately 4. The drug is nonionized and lipid soluble at neutral pH, but it becomes ionized and activated at a pH of less than 3. In its activated state, omeprazole binds to the membrane-bound H^+ - K^+ -adenosine triphosphatase (ATPase) of the parietal cell. Because the compound is a weak base, omeprazole accumulates selectively within the acidic environment of the parietal cell secretory canaliculus; 4 hours after administration, the drug is detectable in appreciable quantities only in the gastric mucosa. If enough drug is administered to occupy all parietal cell-binding sites, anacidity can be produced. Omeprazole, in doses from 20 to 30 mg, causes nearly complete inhibition of stimulated gastric acid secretion within 6 hours. At 24 hours after drug administration, a 60% to 70% reduction in acid secretion persists.

Repeated daily dosing with omeprazole results in increasing inhibitory action on gastric secretion and thus in decreased intragastric degradation of the drug. Acid suppression stabilizes after approximately 3 days. Because of tissue accumula-

tion, the secretory actions of omeprazole do not correlate with plasma levels. Several studies have demonstrated a significant inhibition of peak acid output, marked relief of epigastric pain, and decreased use of supplemental antacids during omeprazole therapy. Direct comparisons with H_2 -receptor antagonists have generally favored omeprazole in terms of pain relief and rate of ulcer healing.

SUCRALFATE

Sucralfate is the aluminum salt of sulfated sucrose. In the acidic environment of the stomach, sucralfate polymerizes, becoming viscous and adhering to the gastroduodenal mucosa. Coating of the ulcer base by the polymer has been claimed to provide a protective barrier, binding bile salts and inhibiting the actions of pepsin. Sucralfate also stimulates the production of mucus. Sucralfate stimulates increased mucosal prostaglandin E_2 production and increases bicarbonate secretion. Sucralfate binds epidermal growth factor and may protect the mitogen from acid degradation. Sucralfate stimulates epithelial proliferation at the ulcer margin. The drug has almost no buffering capacity. Virtually no systemic absorption occurs, and because of this property, sucralfate is safe for the treatment of peptic ulcer in pregnancy.

OPERATIVE TREATMENT OF ULCER DISEASE

Surgical Goals

Operative intervention is reserved for the treatment of complicated ulcer disease. Three complications are most common and constitute the indications for peptic ulcer surgery—hemorrhage, perforation, and obstruction.¹³ The first goal in the surgical treatment of the complications of ulcer disease is treatment of coexisting anatomic complications, such as pyloric stenosis or perforation. The second major goal should be patient safety and freedom from undesirable chronic side effects. To achieve these goals, the gastric surgeon can direct therapy through endoscopic or operative means, the appropriate choice depending on the clinical circumstances.

Operative Procedures

A number of operative procedures have been used to treat peptic ulcer, but with decreasing frequency in the past decade. There is currently no indication for surgical treatment of uncomplicated ulcer disease. Operative treatment of gastric outlet obstruction has decreased by approximately 50%. Most surgical patients are now treated emergently for the complications of bleeding or perforation.

Three procedures—truncal vagotomy and drainage, truncal vagotomy and antrectomy, and proximal gastric vagotomy—have been widely used in the past in the operative treatment of peptic ulcer disease. With increasing frequency, surgical therapy of peptic ulcer is directed exclusively at correction of the immediate problem (e.g., closure of duodenal perforation) without gastric denervation. The underlying ulcer diathesis is then addressed after surgery by antibiotic therapy directed at *H. pylori*. This approach is applicable to most patients with peptic ulcer undergoing emergent operation and predicts a rapidly diminishing role for vagotomy in the future.

Division of both vagal trunks at the esophageal hiatus—truncal vagotomy—denervates the acid-producing fundic mucosa as well as the remainder of the vagally supplied viscera (Fig. 44.1). Because denervation impedes normal pyloric coordination and can result in impairment of gastric emptying,

FIGURE 44.1. Truncal vagotomy and proximal gastric vagotomy. **A:** With truncal vagotomy, both nerve trunks are divided at the level of the diaphragmatic hiatus. **B:** Proximal gastric vagotomy involves division of the vagal fibers that supply the gastric fundus. Branches to the antrum and pyloric region of the stomach are not transected, and the hepatic and celiac divisions of the vagus nerves remain intact.

truncal vagotomy must be combined with a procedure to eliminate pyloric sphincteric function. Usually, gastric drainage is ensured by performance of a pyloroplasty (Fig. 44.2).

Truncal vagotomy can also be combined with resection of the gastric antrum to effect a further reduction in acid secretion, presumably by removing antral sources of gastrin. The limits of antral resection are usually defined by external landmarks, rather than the histologic transition from fundic to antral mucosae. The stomach is divided proximally along a line from a point above the incisura angularis to a point along the greater curvature midway from the pylorus to the gastroesophageal junction. Restoration of gastrointestinal continuity by a gastroduodenostomy is termed a Billroth I reconstruction. A Billroth II procedure uses a gastrojejunostomy (Fig. 44.3).

Proximal gastric vagotomy differs from truncal vagotomy in that only the nerve fibers to the acid-secreting fundic mucosa are divided (see Fig. 44.1). Vagal nerve fibers to the antrum and pylorus are left intact, and the hepatic and celiac divisions are not transected. The operation has also been called parietal cell vagotomy to emphasize its most important functional consequence.

The role of vagotomy in clinical surgery diminished significantly in the 1990s. In 1998, only 7,000 vagotomies were performed in the United States, of more than 41 million operative procedures.¹⁴

Physiologic Consequences of Operation

Division of efferent vagal fibers directly affects acid secretion by reducing cholinergic stimulation of parietal cells. In addition, vagotomy also diminishes parietal cell responsiveness to gastrin and histamine. Basal acid secretion is reduced by approximately 80% in the immediate postoperative period. Acid secretion increases slightly within months of surgery but remains unchanged thereafter. The maximal acid output in response to exogenously administered stimulants such as pentagastrin is reduced by approximately 70% in the early period after surgery. After 1 year, pentagastrin-stimulated maximal acid output rebounds to 50% of prevagotomy values but

FIGURE 44.2. Pyloroplasty formation. **A:** A Heineke-Mikulicz pyloroplasty involves a longitudinal incision of the pyloric sphincter followed by a transverse closure. (*continued*)

FIGURE 44.2. (Continued) **B:** The Finney pyloroplasty is performed as a gastroduodenostomy with division of the pylorus. **C:** The Jaboulay pyloroplasty differs from the Finney procedure in that the pylorus is not transected.

remains at this level on subsequent testing. Acid secretion due to endogenous stimulation by a liquid meal is reduced by 60% to 70% relative to normal subjects.

The inclusion of antrectomy with truncal vagotomy causes further reductions in acid secretion. Pentagastrin-stimulated maximal acid output is reduced by 85% relative to values recorded before surgery. Little rebound in acid secretion occurs with the passage of time.

Truncal vagotomy and proximal gastric vagotomy both cause postoperative hypergastrinemia. Fasting gastrin values are elevated to approximately twice preoperative levels, and the postprandial response is exaggerated. Immediately after vagotomy, hypergastrinemia appears to be due to decreased luminal acid, with loss of feedback inhibition of gastrin release. Loss of vagal inhibitory pathways can also be important. Chronic hypergastrinemia, sustained long term in most cases, is caused by gastrin cell hyperplasia in addition to loss of

inhibitory feedback. When antrectomy is added to vagotomy, circulating gastrin levels are decreased. Basal gastrin values are reduced by approximately half and postprandial gastrin levels by two thirds. The major form of circulating hormone after antrectomy is gastrin 34, released from the duodenum.

Operations that involve vagotomy alter gastric emptying. Proximal gastric denervation abolishes vagally mediated receptive relaxation. Thus, for any given volume ingested, the intragastric pressure rise is greater and the gastroduodenal pressure gradient higher than in normal subjects. As a result, emptying of liquids, which depends critically on the gastroduodenal pressure gradient, is accelerated after proximal gastric vagotomy. Because nerve fibers to the antrum and pylorus are preserved, the function of the distal stomach to mix and triturate solid food is preserved, and emptying of solids is nearly normal in patients who have undergone proximal gastric vagotomy. Truncal vagotomy affects the motor activities of both the proximal and distal

FIGURE 44.3. Antrectomy involves resection of the distal stomach (pink area in inset). Restoration of gastrointestinal continuity may be accomplished as a Billroth I gastroduodenostomy (A) or Billroth II gastrojejunostomy (B) reconstruction.

stomach. Solid and liquid emptying rates are usually increased when truncal vagotomy is accompanied by pyloroplasty.

A number of prospective, randomized trials have compared the various surgical options in terms of postoperative symptoms, including dumping, diarrhea, weight loss, and disturbance of lifestyle (Table 44.3). In most comparisons, proximal gastric vagotomy has proved superior to other operations in these measures. Dumping, a postprandial symptom complex of abdominal discomfort, weakness, and vasomotor symptoms of sweating and dizziness, occurs in 10% to 15% of patients with truncal vagotomy and antrectomy in the early postoperative period and is chronically disabling in 1% to 2%. After truncal vagotomy and pyloroplasty, dumping is present initially in 10%, and remains severe in approximately 1%. Permanent symptoms of dumping are rare after proximal gastric vagotomy. The incidence of diarrhea, which is presumably caused by denervation of the pylorus and small bowel and by elimination of pyloric function, parallels the incidence

TABLE 44.3

RESULTS

CLINICAL RESULTS OF DUODENAL ULCER SURGERY

	PGV (%)	TV + P (%)	TV + A (%)
Mortality rate	0	0.5–1	1–2

Mild	<5	10	10–15
Disabling	0	1	1–2
Diarrhea			
Mild	<5	25	20
Disabling	0	2	1–2

PGV, proximal gastric vagotomy; TV + P, truncal vagotomy and pyloroplasty; TV + A, truncal vagotomy and antrectomy.

of dumping after truncal vagotomy and antrectomy or pyloroplasty. Persistent or disabling diarrhea is present in less than 1% of patients after proximal gastric vagotomy.

Proximal gastric vagotomy has the lowest operative mortality rate. Collected series of proximal gastric vagotomies have reported an operative mortality rate of less than 0.05%, lower than the reported mortality rate for any other gastric procedure for peptic ulcer. Truncal vagotomy and pyloroplasty has a reported mortality rate of 0.5% to 0.8%, whereas the mortality rate after truncal vagotomy and antrectomy approximates 1.5%.

Most prospective surgical series were reported in the era before the pathogenic role of *H. pylori* was appreciated. With appropriate use of postoperative antimicrobials directed against *H. pylori*, ulcer recurrence rates are currently much lower than historical standards. Although recurrence rates (without *H. pylori* treatment) as low as 5% have been reported, a more generally accepted figure is 10%.¹⁵ This rate is similar to that of reinfection with *H. pylori* after its successful eradication. The reported ulcer recurrence rates after proximal gastric vagotomy can be adversely affected by the inclusion of prepyloric and pyloric channel ulcers. For reasons that are not clear, proximal gastric vagotomy is significantly less effective when used to treat ulcers in this position than when used for duodenal ulceration.

Hemorrhage

- 5 Hemorrhage is the leading cause of death associated with peptic ulcer, and the incidence of this complication has not changed since the introduction of H₂-receptor antagonists. The lifetime risk of hemorrhage for patients with duodenal ulcer who have not had surgery and who do not receive continuing maintenance drug therapy approximates 15% at 5 years.¹⁶ Most hemorrhages occur during the initial episode of ulceration or during a relapse, and patients who have hemorrhaged previously have a higher risk of bleeding again. Contin-

ued or recurrent bleeding occurs in 20% to 30% of patients, and when this happens, mortality varies between 10% and 40%. Patients with recurrent hemorrhage and elderly patients are at greatest risk of death, and these two groups should be resuscitated vigorously, investigated promptly, and treated aggressively.¹⁷

The contemporary risk of mortality from bleeding ulcer approximates 10% to 20%. Operative risk is increased in patients who have shock at admission, recurrent bleeding, delay in operative intervention, or coexisting medical illnesses. Surgical delay may lead to recurrent hypovolemia and, subsequently, multisystem organ failure.

Upper gastrointestinal endoscopy is the appropriate initial diagnostic test when hemorrhage from duodenal ulceration is suspected. Endoscopy can correctly determine the site and cause of bleeding in more than 90% of patients. An ulcer should be accepted as the bleeding source only if it has one of the stigmata of active or recent hemorrhage. Active hemorrhage is defined by an arterial jet, active oozing, or oozing beneath an adherent clot. The signs of recent hemorrhage include an adherent clot without oozing, an adherent slough in the ulcer base, or a visible vessel in the ulcer. The ability of these endoscopic findings to accurately predict recurrent hemorrhage has been extensively validated. Approximately 30% of patients who have stigmata of recent hemorrhage experience rebleeding, and most of the patients who experience recurrent hemorrhage require emergency treatment. These stigmata are not sufficiently accurate to be used alone as indications for surgery. Rather, they serve as a warning that aggressive therapy is needed and close follow-up mandatory. The occurrence of hypovolemic shock, rebleeding during hospitalization, and a posteroinferior location of the ulcer are additional clinical features that have been associated with increased risks of recurrent bleeding. The role of gastric acidity as a cause for in-hospital rebleeding appears to be inconsequential, and reduction of acid secretion by H₂-receptor antagonists or omeprazole is not sufficient to prevent recurrent hemorrhage.

The ability to visualize bleeding duodenal ulcers endoscopically has led to development of methods to treat hemorrhage endoscopically. There are many different methods of endoscopic therapy, but the most established consist of thermal coagulation, injection of alcohol, or sclerosants. Thermal coagulation can be achieved by bipolar electrocoagulation or direct application of heat through a heater probe.¹⁸ Injection of epinephrine into the base of the bleeding ulcer is also effective in control of ulcer hemorrhage.

Proof of efficacy, in the form of lowered rebleeding rates and avoidance of operation, has been convincingly demonstrated for all of these methods of endoscopic hemostasis. The analysis of reports of endoscopic treatment of hemorrhage is complicated by the 70% rate of spontaneous, although sometimes temporary, cessation of bleeding without intervention. In addition to endoscopic stigmata, hemodynamic instability, need for continuing transfusion, red stool or hematemesis, age older than 60 years, and serious medical comorbidity are clinical features that mandate endoscopic therapy. Rebleeding during hospitalization and the endoscopic findings of visible vessel, oozing, or bleeding associated with an adherent clot are other indications for endoscopic hemostasis. Ulcers with clean bases require no treatment. Failure of endoscopic hemostasis is usually due to inaccessibility because of scarring, to rapid active bleeding obscuring the endoscopic view, or to an adherent clot. Patients treated endoscopically should be observed closely for further hemorrhage. Patients who rebleed within 72 hours of initial endoscopic control may be successfully retreated without increasing the risk of mortality.¹⁹

The efficacy of endoscopy is dependent on timing. Early endoscopy correctly identifies patients at low risk for recurrent

TABLE 44.4 INDICATIONS/CONTRAINDICATIONS

SITUATIONS IN WHICH OPERATIVE INTERVENTION IS APPROPRIATE

Massive hemorrhage leading to shock or cardiovascular instability
Prolonged blood loss requiring continuing transfusion
Recurrent bleeding during medical therapy or after endoscopic therapy
Recurrent hemorrhage requiring hospitalization

hemorrhage and permits safe avoidance of hospitalization. Early endoscopy also benefits high-risk patients by directing active hemostatic therapy. Patients treated in this way have been demonstrated to have fewer episodes of rebleeding, lower rates of operation, and shorter hospitalizations.

Table 44.4 lists situations in which operative intervention is appropriate. The need for emergency surgery significantly increases surgical risks; mortality rates are increased approximately 10-fold. Operative therapy should consist of duodenotomy with direct ligation of the bleeding vessel in the ulcer base.

Postoperatively, patients should receive antibiotics directed against *H. pylori*. This treatment paradigm is based on the observation that peptic ulcer hemorrhage recurs in 20% of patients in whom *H. pylori* is not eradicated, whereas rebleeding is reduced to 3% in patients who receive *H. pylori* eradication therapy²⁰ (Algorithm 44.1). The studies that support this practice were not specifically designed to evaluate postoperative hemorrhage, but the results are so definitive that they support this application (Fig. 44.4).

Perforation

The lifetime risk for perforation in patients with duodenal ulceration who do not receive therapy approximates 10%. In contrast, ulcer perforation is unusual if initial ulcer healing has been achieved.

Perforation of a duodenal ulcer is usually accompanied by sudden and severe epigastric pain. The pain, caused by the

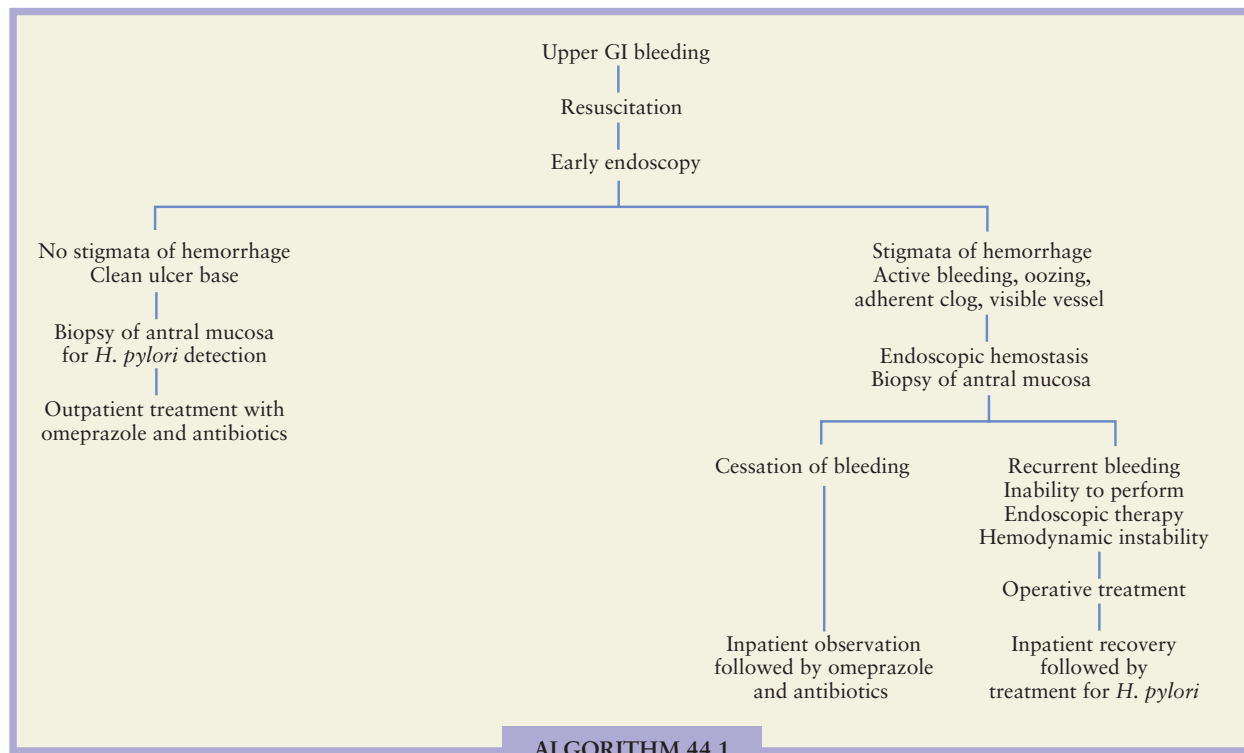

FIGURE 44.4. Probability of freedom from recurrent hemorrhage according to posttreatment *Helicobacter pylori* status.

ALGORITHM 44.1 Treatment of bleeding duodenal ulceration.

spillage of highly caustic gastric secretions into the peritoneum, rapidly reaches peak intensity and remains constant. Radiation to the right scapular region is common because of right subphrenic collection of gastric contents. Occasionally, pain is sensed in the lower abdomen if gastric contents travel caudally through the paracolic gutter. Peritoneal irritation is usually intense, and most patients avoid movement to minimize discomfort.

Physical examination reveals low-grade fever, diminished bowel sounds, and rigidity of the abdominal musculature. Usually, upright abdominal radiographs reveal pneumoperitoneum, but up to 20% of perforated ulcers do not show free intraperitoneal air. Computed tomography of the abdomen is very sensitive for demonstrating perforation if pneumoperitoneum is not demonstrated but perforation is still suspected.

Although occasional reports have described the nonoperative treatment of this complication, perforation remains a strong indication for surgery in most circumstances. Laparotomy or laparoscopy affords the opportunity to relieve intraperitoneal contamination and to close the perforation (Fig. 44.5).

Signs of antecedent duodenal ulceration, in terms of history of prior symptoms and anatomic evidence of duodenal scarring, should be sought. A lack of antecedent symptoms is not protective. Reports suggest that patients without antecedent symptoms are also at risk for recurrent ulceration. By 5 to 6 years, symptomatic ulcer recurrence in patients with acute ulcer perforation is similar to that for patients with chronic disease. Before the role of *H. pylori* was appreciated, simple omental closure of duodenal perforation resulting from chronic ulceration did not provide satisfactory long-term results; up to 80% of patients so treated had recurrent ulceration, and 10% experienced reoperation if untreated. Approximately four fifths of all patients with perforation have

FIGURE 44.5. Omental patching of perforated duodenal ulcer.

FIGURE 44.6. Schematic representation of balloon dilatation of pyloric stenosis.

H. pylori infestation and therefore are at risk of recurrent disease.

The mortality of emergent ulcer operations is most clearly correlated with the following circumstances: preoperative shock, coexisting medical illness, and presence of perforation for more than 48 hours.²¹

- 6 Current reports advocate omental patch closure only, often laparoscopically, with postoperative anti-*H. pylori* therapy. This approach presumes that most duodenal ulcers are caused by *H. pylori*, that secure closure of the perforation can be obtained, and that further surgical therapy will be obviated by the effects of medical therapy. Minimally invasive approaches are becoming standard practice.

Two meta-analyses of surgical treatment of perforated peptic ulcer have compared open surgical therapy with laparoscopic approaches.^{22,23} In terms of operative time, there is no clear superiority of one approach over the other, but all trials reported after 2001 have favored laparoscopic repair. While in-hospital analgesic use is less in laparoscopically treated patients, the more important variable of hospital length of stay was not significantly shorter for these patients. Overall rates of postoperative complications were not statistically different between the two approaches. A lower rate of wound infection in the laparoscopic group approached significance. Return to normal daily activities and work favored the laparoscopic group. The pooled estimate of mortality favored laparoscopic repair.

Obstruction

Gastric outlet obstruction can occur acutely or chronically in patients with duodenal ulcer disease. Acute obstruction is caused by edema and inflammation associated with ulcers in the pyloric channel and the first portion of the duodenum. Pyloric obstruction is suggested by recurrent vomiting, dehydration, and hypochloremic alkalosis due to loss of gastric secretions. Acute gastric outlet obstruction is treated with nasogastric suction, rehydration, and intravenous administration of antisecretory agents. In most instances, acute obstruction resolves with such supportive measures within 72 hours.

Repeated episodes of ulceration and healing can lead to pyloric scarring and a fixed stenosis with chronic gastric outlet obstruction.²³ In cases of untreated duodenal ulceration, the lifetime risk of chronic pyloric stenosis approximates 10%.

Upper endoscopy is indicated to confirm the nature of the obstruction and to exclude neoplasm. Endoscopic hydrostatic balloon dilatation of pyloric stenoses can also be attempted at this time (Fig. 44.6). Approximately 85% of pyloric stenoses are amenable to balloon dilatation. Only 40% of patients with gastric stenoses have sustained improvement by 3 months after balloon dilatation. Recurrent stenoses are presumably due to residual scarring in the pyloric channel. Thus, although pyloric dilatation is occasionally palliative, in most cases operative correction is required.

Operative management of gastric outlet obstruction should be focused on relief of the anatomic abnormality. Antrectomy has been used with success in this circumstance, with low ulcer recurrence rates and with satisfactory restoration of gastric emptying.

GASTRIC ULCER

Benign gastric ulcers are a form of peptic ulcer disease, occurring with one-third the frequency of benign duodenal ulceration. In the United States, gastric ulcer is somewhat more common in men than in women and occurs in a patient cohort approximately 10 years older than for duodenal ulceration.

Endoscopic Diagnosis

Upper gastrointestinal endoscopy is the preferred method for diagnosing gastric ulceration. The ulcer base in benign disease is commonly smooth and flat and often covered by a gray, fibrous exudate. The margin is usually slightly raised, erythematous, and friable. Differentiation of benign and malignant gastric ulcers is reliably made only by histologic examination. Visual endoscopic differentiation of benign from malignant ulcers is not reliable. All gastric ulcers should have multiple biopsies taken from the perimeter of the lesion. The addition of lesional brushings to biopsy increases diagnostic accuracy to approximately 95%.

Benign gastric ulcers may occur in any location in the stomach, but approximately 60% are located along the lesser curvature proximal to the incisura angularis. Less than 10% of benign gastric ulcers are located on the greater curvature. Virtually all gastric ulcers lie within 2 cm of the histologic transition between fundic and antral mucosa. With increasing age, this mucosal transition zone moves proximally along the lesser

curvature. Movement of this transition zone is reflected by the greater prevalence of proximal ulcers in elderly patients.

As with benign duodenal ulceration, *H. pylori* plays a central role in the pathogenesis of benign gastric ulcers.²⁵ Benign gastric ulcers associated with *H. pylori* respond to antibiotic therapy at a rate equivalent to that of duodenal ulceration. The recurrence rate of ulcerations in these patients after *H. pylori* eradication is equal to the rate of reinfection.

A strong association of benign gastric ulceration with the use of NSAIDs has been recognized. Cigarette smoking is associated with development of gastric ulceration, and continued smoking impedes medical therapy. Gastric and duodenal ulcers have been noted in patients receiving hepatic artery chemotherapy in whom improper placement of the catheter permits perfusion of gastric and duodenal mucosae. A variety of agents, including 5-fluorouracil, cisplatin, doxorubicin, and mitomycin C, have been implicated.

Therapy

The primary therapy for benign gastric ulceration in most patients is antimicrobial treatment of *H. pylori* infection. The treatment protocols are similar to those used for benign duodenal ulceration. For many patients, cessation of NSAID therapy is also required.

Indications for surgical treatment of gastric ulcer include hemorrhage, perforation, failure of a recurrent ulcer to respond to medical therapy, and inability to exclude malignant disease.

For benign gastric ulcers, the elective operation of choice is usually a distal gastrectomy with gastroduodenal (Billroth I) anastomosis. The ulcer should be included in the gastrectomy specimen. With this approach, operative mortality rates of 2% to 3%, with ulcer recurrence rates of less than 5%, have been reported. Because benign gastric ulcers are not associated with gastric acid hypersecretion, inclusion of vagotomy is not necessary.

The occurrence of a gastric ulcer near the gastroesophageal junction represents a difficult surgical problem. When possible, the ulcer should be excised. This usually requires a distal gastrectomy with an extension along the lesser curvature near the esophageal wall and reconstruction with gastrojejunostomy.

Emergency operations performed for hemorrhage or perforation require ulcer excision. Distal gastrectomy, performed with gastroduodenal reconstruction, is usually the procedure of choice. Operative mortality rates average 10% to 20% in the presence of hemorrhage or perforation.

POSTGASTRECTOMY SYNDROMES

A number of syndromes have been described that are associated with distressing symptoms after gastric operations performed for peptic ulcer or gastric neoplasm. The occurrence of severe postoperative symptoms is fortunately low, perhaps 1% to 3% of cases, but the disturbances can be disabling. The two most common postgastrectomy syndromes, categorized according to predominant manifestation, are dumping and alkaline reflux gastritis.

Dumping

The term *dumping* denotes a clinical syndrome with both gastrointestinal and vasomotor symptoms. The precise cause of dumping is not known but is believed to relate to the unmeted entry of ingested food into the proximal small

bowel after vagotomy and either resection or division of the pyloric sphincter. Early dumping symptoms occur immediately after a meal and include nausea, epigastric discomfort, borborygmi, palpitations, and, in extreme cases, dizziness or syncope. Late dumping symptoms follow a meal by 1 to 3 hours and can include reactive hypoglycemia in addition to the aforementioned symptoms.

Although a relatively large number of patients experience mild dumping symptoms in the early postoperative period, minor dietary alterations and the passage of time bring improvement in all but approximately 1%. The somatostatin analogue octreotide has been reported to improve dumping symptoms when 50 to 100 mg is administered subcutaneously before a meal. The beneficial effects of somatostatin on the vasomotor symptoms of dumping are postulated to be due to pressor effects of the compound on splanchnic vessels. In addition, somatostatin analogues inhibit the release of vasoactive peptides from the gut, decrease peak plasma insulin levels, and slow intestinal transit, all effects that might be expected to ameliorate dumping symptoms. Octreotide administration before meal ingestion has been shown to prevent changes in pulse, systolic blood pressure, and packed red cell volume during early dumping and blood glucose levels during late dumping.

Alkaline Reflux Gastritis

The term *alkaline reflux gastritis* should be reserved for patients who demonstrate the clinical triad of postprandial epigastric pain often associated with nausea and vomiting, evidence of reflux of bile into the stomach, and histologic evidence of gastritis. One or more of these findings occur transiently in 10% to 20% of patients after gastric resection, but they persist in only 1% to 2%.

The differential diagnosis for a patient with postoperative epigastric pain includes recurrent ulceration, biliary and pancreatic disease, afferent loop obstruction, and esophagitis in addition to alkaline reflux gastritis. Gastric acid analysis shows basal hypochlorhydria with little increase with pentagastrin stimulation. Serum gastrin measurements should be determined to exclude Zollinger-Ellison syndrome and retained gastric antrum. Endoscopic examination is essential to exclude recurrent ulcer.

Endoscopically, the gastric mucosa appears red, friable, and edematous. Gastric inflammation is patchy and nonulcerative. Histologic examination shows mucosal and submucosal edema and infiltration of acute and chronic inflammatory cells into the lamina propria. Glandular atrophy and intestinal metaplasia are frequent accompaniments.

No perfect solution to alkaline reflux gastritis exists. Antacids, H₂-receptor antagonists, bile acid chelators, and dietary manipulations have not been demonstrated definitely to be beneficial. The only proved treatment for alkaline reflux gastritis is operative diversion of intestinal contents from contact with the gastric mucosa. The most common surgical procedure used for this purpose is a Roux-en-Y gastrojejunostomy with an intestinal limb of 50 to 60 cm constructed to prevent reflux of intestinal contents (Fig. 44.7). This procedure is effective in eliminating bilious vomiting (nearly 100%), but recurrent or persistent pain is reported in up to 30% of patients, and up to 20% of patients are troubled with postoperative delayed gastric emptying.

STRESS GASTRITIS

- 7 Major trauma accompanied by shock, sepsis, respiratory failure, hemorrhage, or multiorgan injury is often accompanied by acute stress gastritis.²⁶ Acute stress gastritis is particularly prevalent after thermal injury with greater than 35% total surface area burned. A similar entity is also observed as a

FIGURE 44.7. Conversion of Billroth II gastrojejunostomy to Roux-en-Y gastrojejunostomy. The afferent limb is divided (A), and intestinal continuity is re-established by anastomosis 50 to 60 cm downstream from the original gastrojejunostomy (B).

result of central nervous system injury or intracranial hypertension. Multiple superficial ulcerations and erosions are noted in the proximal, acid-secreting portion of the stomach, with fewer lesions in the antrum and only rare ulcerations in the duodenum.

The most sensitive diagnostic test for stress ulceration is endoscopic examination. If patients are examined within 12 hours of the onset of injury, acute mucosal ulcerations may be observed that appear as multiple, shallow areas of erythema and friability, often accompanied by focal hemorrhage. The lesions are progressive during the first 72 hours after injury. When lesions are examined histologically, they are seen to consist of coagulation necrosis of the superficial endothelium with infiltration of leukocytes into the lamina propria. Chronic disease, characterized by fibrosis and scarring, is not observed. With resolution of the underlying injury or sepsis, healing is accompanied by mucosal restitution and regeneration.

Clinical observations and a large number of experimental studies suggest that mucosal ischemia is the central event underlying the development of stress gastritis. In clinical practice, most patients who contract stress gastritis do so after an episode of sepsis, hemorrhage, or cardiac dysfunction accompanied by shock.²⁷ Experimental studies that cause depletion of high-energy phosphate compounds such as ATP predispose to the development of stress gastritis. Luminal gastric acid secretion, although not the sole cause of stress gastritis, appears to be a necessary concomitant process. A number of experimental observations suggest that a critical concentration of luminal acid is required to initiate injury in the setting of mucosal ischemia. The fall in mucosal energy supply permits proton back-diffusion into the mucosa; the resultant decrease in mucosal pH exacerbates ischemic damage.

Clinical risk factors that predict development of stress gastritis include adult respiratory distress syndrome, multiple

long-bone fractures, a major burn over 35% of the body surface, transfusion requirement above 6 units, hepatic dysfunction, sepsis, hypotension, and oliguric renal failure. Scoring systems of critical illness, exemplified by the Acute Physiology and Chronic Health Evaluation (APACHE) system, accurately predict risk for acute stress gastritis.

The major complication of stress gastritis is hemorrhage. Admission to an intensive care unit is not an independent risk factor for bleeding. However, the development of respiratory failure or coagulopathy (platelet count less than 50,000/mm³, international normalized ratio [INR] >1.5, or partial thromboplastin time [PTT] greater than two times normal) imparts the greatest risk for hemorrhage.

Diagnosis

Clinical studies that use bloody nasogastric discharge as a sign of stress gastritis probably underestimate its incidence in critically ill patients. Conversely, studies based on endoscopy overestimate the incidence of clinically important stress gastritis. In one endoscopically controlled study, 100% of patients with life-threatening injuries had evidence of gastric erosions by 24 hours. Severely burned patients have endoscopic evidence of gastric erosions in greater than 90% of cases, whereas significant upper gastrointestinal hemorrhage occurs in between 25% and 50% of patients with burn wound infection.

Barium contrast examinations have no role in the diagnosis of stress gastritis and interfere with subsequent endoscopic examination. Analysis of gastric contents for titration of acid production is not informative.

Treatment and Prophylaxis

All critically ill patients are at risk for development of acute stress gastritis. Because hemorrhage associated with stress gastritis significantly increases mortality, all such patients should be treated prophylactically.²⁸

Stress gastritis prophylaxis has focused on control of gastric luminal pH. If intragastric pH can be maintained above 3.5, effective prophylaxis can be obtained. In one study of seriously ill patients, antacid prophylaxis decreased bleeding from 25% to 4% of patients.

A number of prospective studies suggest that administration of H₂ antagonists are as effective as antacids for prophylaxis of stress gastritis.²⁹ Infusion of an H₂ antagonist at a rate that maintains intraluminal gastric pH at greater than 3.5 is equally effective, relative to antacids, in terms of prevention of bleeding. Continuous-infusion H₂-receptor antagonist therapy appears to be equally effective relative to intermittent dosing with H₂ blockers or antacids. Proton pump inhibitors have also been shown to be effective as stress ulcer prophylaxis.

When stress gastritis causes gastrointestinal bleeding, endoscopic therapy is used as first-line treatment. Endoscopic examination is diagnostic and permits application of electrocautery or heater probe hemostasis.

Only a small minority of patients with acute stress gastritis and hemorrhage require operative therapy. The surgical approach should control acute bleeding, have a low risk of recurrent hemorrhage, and be associated with a low operative mortality rate. No procedure meets all of these criteria, and no large clinical experience is available to confirm the superiority of one procedure over another. Total gastrectomy is associated with the lowest risk of recurrent bleeding but has a mortality

rate of approximately 20%. Procedures such as vagotomy and pyloroplasty, vagotomy and antrectomy, and vagotomy and subtotal gastrectomy are each associated with high risks of recurrent hemorrhage.

CHAPTER 45 ■ MORBID OBESITY

REBECCA P. PETERSEN, CHRISTOPHER J. MYERS, AND ERIC J. DeMARIA

KEY POINTS

- 1 Overweight and obesity can be quantified by body mass index (BMI), which is calculated as weight in kilograms divided by the square of the height in meters.
- 2 Two thirds of the U.S. adult population is considered overweight (BMI ≥ 25 kg/m²) and half of these are obese (BMI ≥ 30 kg/m²).
- 3 Obesity is associated with numerous comorbidities including diabetes and atherosclerosis, respiratory and cardiac failure, venous thromboembolic disease, cholelithiasis, degenerative joint disease, pseudotumor cerebri, and non-alcoholic steatohepatitis.
- 4 Patients are considered eligible for surgical treatment of obesity if they have a BMI greater than or equal to 40 kg/m² without an obesity-related comorbidity or a BMI greater than or equal to 35 kg/m² with an obesity-related comorbidity (e.g., diabetes, respiratory insufficiency, pseudotumor cerebri).
- 5 A National Institutes of Health Technology Assessment Conference in 1992 concluded that dietary management of severe obesity, with or without behavioral modification, failed to provide acceptable evidence of long-term efficacy.
- 6 Adjustable gastric banding and gastroplasties are restrictive procedures that have been performed with either horizontal or vertical placement of the staples.
- 7 Gastric bypass combines restriction and malabsorption to assist weight loss.

Obesity and overweight have now reached epidemic proportions, and their associated conditions have serious implications for global health. Traditionally, categories of obesity and overweight have been defined using body mass index (BMI), which is calculated as weight in kilograms divided by the square of the height in meters. Thresholds to classify overweight, obesity, and morbid obesity have been created based on long-term outcome.

- 2 According to this classification, more than two thirds of the U.S. adult population is overweight and half of these are obese, which has important public health implications because obesity is clearly associated with increased morbidity and mortality.^{1,2} In addition, this crisis now involves the developing world, and the World Health Organization (WHO) currently estimates that 1.7 billion people worldwide are overweight or obese.³ Alarming, obesity has become increasingly prevalent in the pediatric population, and 30% of U.S. children have a BMI greater than the 85th percentile for their age.⁴
- 3 Severe obesity is associated with a large number of associated comorbidities, many of which are associated with an increased risk of mortality (Table 45.1) and include coronary artery disease, hypertension, heart failure, type 2 diabetes mellitus, obesity hypoventilation and sleep apnea syndromes, hypercoagulability and venous thromboembolic disease, necrotizing panniculitis, diverticulitis, and necrotizing pancreatitis. In addition, morbidly obese patients have an increased risk of colon, prostate, breast, and uterine carcinoma.

- 4 The 1991 National Institutes of Health (NIH) Consensus Panel (Table 45.2) established eligibility criteria for surgical management. In general, a BMI greater than or equal to 40 kg/m² without an associated comorbidity and a BMI greater than or equal to 35 kg/m² with an established comorbidity are considered general criteria for consideration of surgical management of obesity.

and environmental factors. Multiple studies have identified a genetic predisposition to obesity, and several genetic markers have been described. In adoption studies, severity of obesity was found to be more concordant with the natural than the adoptive parents.^{5,6} Furthermore, monozygotic twins have more similar weights than dizygotic twins, even if they grow up in different environments.^{7,8}

Gastrointestinal and neuroendocrine peptides are involved in weight homeostasis, in conjunction with neural or humoral transmitters to the hypothalamic hunger or satiety centers, and the psychologically induced oral dependency drive. Ghrelin, a potent orexigenic peptide secreted by the stomach, increases in response to fasting and decreases postprandially. Ghrelin levels are decreased in obese individuals.⁹ The adipocyte hormone leptin stimulates anorexigenic neuropeptides in the hypothalamus to inhibit food intake; obese individuals often have increased serum levels of leptin and may be resistant to leptin effects on food intake and energy expenditure.¹⁰ This is supported by studies demonstrating that morbidly obese adults have been found to have a lower basal energy expenditure.¹¹

The distribution of body fat is an important characteristic, as android or central obesity has been associated with significantly worse long-term health compared with gynoid or peripheral obesity. Anthropomorphic measurements such as the waist-to-hip ratio have been used to quantify central obesity; however, computed tomography scans have shown that abdominal circumference is a more accurate measurement of central fat distribution.⁸ The increased metabolic activity of mesenteric fat is associated with increased metabolism of amino acids to carbohydrates, leading to hyperglycemia and hyperinsulinemia. Hyperinsulinemia gives rise to increased sodium absorption and hypertension and insulin resistance. Central abdominal obesity has also been associated with dyslipidemia, including low high-density lipoprotein (HDL) cholesterol and elevated triglycerides, increased systemic inflammation, and hypercoagulability. As these conditions tend to track together, collectively these conditions are referred to as the metabolic syndrome. Other conditions associated with obesity include increased fatty acid and cholesterol turnover with an increased risk of atherosclerosis

ETIOLOGY

The causes of morbid obesity are not entirely known but likely include a combination of genetic, endocrinologic, behavioral,

TABLE 45.1**MORBIDITY OF OBESITY**

Cardiovascular dysfunction
Hypertension
Coronary artery disease
Heart failure
Type 2 diabetes mellitus (adult onset or non–insulin dependent)
Nonalcoholic steatohepatitis
Respiratory insufficiency of obesity (pickwickian syndrome)
Obesity hypoventilation syndrome
Obstructive sleep apnea syndrome
Increased intra-abdominal pressure
Stress overflow urinary incontinence
Gastroesophageal reflux
Venous disease
Thrombophlebitis
Stasis ulcers
Pulmonary embolism
Nephrotic syndrome
Pseudotumor cerebri
Degenerative osteoarthritis
Cholelithiasis
Infectious complications
Difficulty recognizing peritonitis
Necrotizing subcutaneous infections
Wound infections or dehiscence
Sexual hormone dysfunction
Polycystic ovary (Stein-Leventhal) syndrome

and cholelithiasis, polycystic ovary (Stein-Leventhal) syndrome, and nonalcoholic steatohepatitis.⁷

CONDITIONS ASSOCIATED WITH MORBID OBESITY

An important consequence of central obesity is increased intra-abdominal pressure, which contributes to many of the conditions associated with morbid obesity. In addition to the conditions in this section, gastroesophageal reflux, stress or urge urinary incontinence, nephrotic syndrome, and incisional and inguinal hernias are common problems in obese patients.^{12,13}

TABLE 45.2 INDICATIONS/CONTRAINDICATION**CRITERIA FOR PATIENT SELECTION FOR BARIATRIC SURGERY**

Body mass index >40 kg/m ²
Body mass index >35 kg/m ² with coexisting comorbidities
Failure of nonsurgical methods of weight reduction
Psychological stability
Absence of drug and alcohol abuse

Respiratory Disorders Associated with Obesity

There are two components of respiratory dysfunction in obesity—obstructive sleep apnea syndrome (OSA) and obesity hypoventilation syndrome (OHS)—and collectively these conditions comprise the pickwickian syndrome. Both of these conditions may be present before operation but may be exacerbated by a surgical procedure. Following gastric surgery for obesity, OSA and OHS can completely resolve.¹⁴

OSA is a potentially fatal complication of morbid obesity and is characterized by frequent daytime somnolence and heavy snoring. The frequent episodes of apnea result in inadequate stage IV and rapid eye movement (REM) sleep, leading to somnolence during the day. Patients with suspected sleep apnea syndrome should undergo preoperative polysomnography at a sleep center to confirm the diagnosis and to guide therapy. During surgical procedures, patients with OSA are at great risk for acute upper airway obstruction and respiratory arrest at the time of anesthetic induction. In severe cases, it may be worthwhile to consider elective tracheostomy prior to bariatric surgery.

Obesity Hypoventilation Syndrome

OHS is a condition in which an obese patient suffers from hypoxemia and hypercapnia when breathing room air while awake but resting.¹⁵ As many alveolar units are collapsed at end expiration, considerable ventilation/perfusion (V/Q) mismatch occurs, leading to shunting, hypoxemia, and hypercapnia. The condition is not directly associated with the degree of obesity, and among patients undergoing gastric bypass surgery, no statistically significant difference in weight was found between those who had OHS and those who did not.¹⁴ The diagnosis can be confirmed with spirometry and arterial blood gas analysis.

Chronic pulmonary arterial hypoxemia leads to severe pulmonary hypertension and subsequent right-sided heart failure, manifested by jugular venous distention, tricuspid valve regurgitation, right upper quadrant tenderness due to acute hepatic engorgement, and massive peripheral edema.^{16,17}

Cardiac Dysfunction

Cardiac dysfunction in the morbidly obese patient is often associated with respiratory disorders of obesity.¹⁰ Elevated pulmonary pressures are secondary to hypoxemia-induced pulmonary arterial vasoconstriction and increased pleural pressures transmitted by elevated intra-abdominal pressure (IAP).^{16,18,19} In obese patients, circulating blood volume, plasma volume, and cardiac output increase in proportion to body weight, but massively obese patients may occasionally present with high-output heart failure, which is likely due to the enormous circulatory and metabolic requirements of such patients.²⁰ Significant weight loss has been demonstrated to correct pulmonary hypertension as well as left ventricular dysfunction associated with respiratory insufficiency.^{16,21}

Venous Thromboembolic Disease

Morbidly obese individuals are markedly predisposed to venous thromboembolic disease, as they tend to be sedentary and have a large amount of abdominal weight resting on the inferior vena cava and have increased intrapleural pressure, which impedes venous return.^{17,18} Low levels of antithrombin may also increase the tendency toward venous thrombosis.²²

Venous stasis ulcers in patients with morbid obesity are almost impossible to cure due to elevated venous pressure. In addition to standard treatments for stasis ulcers, a critical goal in obese patients is weight loss. Significant improvements in weight almost invariably lead to healing of the ulcer and are probably the result of decreased IAP and venous pressure.²³

Gallstones

Approximately one third of morbidly obese patients have cholelithiasis. Many have either had a cholecystectomy or had gallstones noted during another intra-abdominal operative procedure. In addition, rapid weight loss has been associated with development of gallstones in 25% to 40% of patients who undergo gastric bypass procedures. The risk of cholelithiasis in this setting can be reduced to 2% by administering ursodeoxycholic acid, 300 mg orally twice daily.²⁴

Preoperative evaluation of the gallbladder may be technically quite difficult in morbidly obese patients because gallstones may be missed with transcutaneous ultrasonography. Among patients with symptoms of cholelithiasis, intraoperative sonography is a useful procedure to characterize cholelithiasis. Consideration should be given to cholecystectomy in a patient undergoing gastric operation for obesity.

Pseudotumor Cerebri

Pseudotumor cerebri is an unusual complication of morbid obesity that is associated with benign intracranial hypertension, papilledema, blurred vision, headache, and elevated cerebrospinal fluid pressures.²⁵ Currently, there is no evidence that patients with pseudotumor cerebri are at any additional perioperative risk, and cerebrospinal fluid does not have to be removed or shunted before anesthesia and major abdominal operations. Importantly, successful weight reduction will lead to resolution of pseudotumor cerebri.^{26,27}

Degenerative Osteoarthritis

Degenerative osteoarthritis of the knees, hips, and back is a common complication of morbid obesity. In addition, podiatric pain is quite common. Weight reduction alone may greatly reduce the pain and immobility that afflict these patients, although many patients may require total joint replacement. Of note, joint replacement in patients who weigh more than 250 lb is associated with an unacceptable incidence of loosening, highlighting the importance of weight reduction prior to aggressive orthopedic interventions in morbidly obese patients.²⁸ Given the significant limitations of conservative weight loss programs in patients with severe degenerative joint disease, weight reduction by means of a gastric bariatric operation may be the most sensible initial approach, followed by repeat orthopedic evaluation if pain and dysfunction persist.

MEDICAL MANAGEMENT OF MORBID OBESITY

There are many dietary programs for weight reduction, including hospital-supervised programs, psychiatric behavioral modification programs, commercial organizations, commercial diets, protein-sparing fast programs, and medications. Unfortunately, while many people can lose weight successfully through dietary manipulation, only 5% to 10% of patients with extreme obesity are able to sustain significant weight reduction.²⁹ An NIH Technology Assessment Conference in 1992 concluded that dietary management of severe

obesity, with or without behavioral modification, failed to provide acceptable evidence of long-term efficacy.²³ Pharmacotherapy includes orlistat, a pancreatic lipase inhibitor that blocks fat absorption, and sibutramine, which works as an appetite suppressant. These agents provide only modest weight loss and are inadequate therapy for the morbidly obese patient.²⁴

SURGICAL MANAGEMENT OF MORBID OBESITY

Eligibility for Obesity Surgery

The mortality risk for patients undergoing gastric bypass can now be assessed by the Obesity Surgery Mortality Risk Score (OS-MRS), which is composed of five independent, preoperative clinical variables and predicts 90-day mortality after gastric bypass surgery (Table 45.3). The OS-MRS was derived from 2,075 patients undergoing gastric bypass surgery at a single institution, and validation of the OS-MRS has been completed in a multicenter study involving 4,431 patients from four institutions. The OS-MRS is a valuable tool that can be used to stratify risk and aid in surgical decision making and patient discussion in bariatric surgery.⁶

While morbid obesity does impose greater perioperative risk, the risk can be markedly reduced by appropriate preoperative and postoperative care. Specifically, these risks include wound infection, dehiscence, thrombophlebitis, pulmonary embolism, anesthetic calamities, acute postoperative asphyxia in patients with OSA, acute respiratory failure, right ventricular or biventricular cardiac failure, and missed acute catastrophes of the abdomen, such as an anastomotic leak (Table 45.4).

Periprocedure Considerations

Morbidly obese patients are at significant risk of coronary artery disease as a result of the increased prevalence of coronary risk factors including systemic hypertension, dyslipidemia, insulin resistance, and diabetes. Thus, preoperative

TABLE 45.3

electrocardiography should be performed on all obese patients 30 years of age or older, and abnormal findings worrisome for underlying coronary artery disease should be pursued.

Morbidly obese patients with a history of pulmonary disease or a BMI greater than 50 kg/m² should have preoperative determinations of blood gas values. If arterial blood gas (ABG) measurement reveals severe hypoxemia (partial pressure of arterial oxygen [PaO₂] ≤55 mm Hg), severe hypercapnia (partial pressure of arterial carbon dioxide [PaCO₂] ≥47 mm Hg), or both, consideration should be given to right heart catheterization prior to surgery. Morbidly obese patients may also have significantly elevated pulmonary artery wedge pressure (PAWP), which may indicate left ventricular dysfunction.¹⁶ It is highly probable that some of the elevated pulmonary artery pressure (PAP) and PAWP measurements are caused by the increased IAP in the morbidly obese.^{18,30} Typically, this is manifested by an elevated diaphragm, which in turn increases intrapleural pressure and subsequently PAP and PAWP. Pleural pressure can be measured with an esophageal transducer in conjunction with a right heart catheter and the transmural pressure can be estimated. For this reason, these patients may require a markedly elevated PAWP to maintain an adequate cardiac output, and excessive diuresis may lead to hypotension.

If PAWP is greater than or equal to 18 mm Hg, diuresis with intravenous furosemide should be administered before elective operation. In some cases, low cardiac output and hypotension may follow diuresis. These patients may require higher than normal ventricular filling pressures, requiring some volume reexpansion. It is important to identify the optimal filling pressures for patients based on relative changes in cardiac output in response to either volume challenge or diuresis in morbidly obese patients.

Morbidly obese patients should be placed in the reverse Trendelenburg position to maximize diaphragmatic excursion and to increase residual lung volume.³¹ In a supine position, these patients will often complain of air hunger and respiratory distress, and breaking of the bed at the waist may exacerbate the problem by pushing the abdominal contents into the chest by raising the diaphragm and further reducing lung volumes.

During surgical procedures, patients with OSA are at great risk for acute upper airway obstruction and respiratory arrest at the time of anesthetic induction. Obese patients with respiratory disorders pose the greatest challenge because they often have a short neck with considerable adipose tissue and a heavy chest wall, both of which create challenges for successful intubation and adequate ventilation. If endotracheal intubation proves too difficult, these patients can be well ventilated with a mask. Awake intubation can be performed, with or without fiberoptic aids, but is quite unpleasant and rarely necessary.

An oral airway is strongly recommended after muscle paralysis due to the redundant tissue of the soft palate. In general, it is useful if one anesthetist is responsible for airway positioning, including two-handed seal of the mask, and the second anesthetist is responsible for adequate ventilation, including two-hand compression of the ventilation reservoir bag. Intubation should only be attempted after ventilation with 100% oxygen for several minutes and attempts at intubation should be limited to no longer than 30 seconds. If the patient has severe OSA and continuous positive airway pressure (CPAP) is ineffective or cannot be tolerated, a tracheostomy should be considered. Often, an extra-long tracheostomy tube is necessary due to excess adipose tissue.

Three high-risk complications of chronic and severe hypoxemia for OHS patients are polycythemia, pulmonary arterial vasoconstriction, and pulmonary hypertension. Polycythemia further increases the already significant risk for venous thrombosis and pulmonary embolism, and in general if the hemoglobin (Hb) concentration is greater than or equal to 16 g/dL, phlebotomy to a concentration of 15 g/dL should be performed to reduce the postoperative risk of venous thrombosis. In patients with OHS, oxygen administration is occasionally associated with worsening CO₂ retention and hypoventilation, potentially prolonging intubation and mechanical ventilation. Because pulmonary disease is typically restrictive rather than obstructive, obese patients are often easy to ventilate without high peak airway pressures. In considering extubation, achieving normal arterial blood gas values is not necessary; only a return to the baseline preoperative values is needed. In patients undergoing a major open upper abdominal operation, this can be achieved on average 4 days postoperatively when patients experience a decrease in incisional pain, particularly with the laparoscopic technique.³²

In the perioperative setting, obese patients are most at risk for thromboembolic events when immobilized in the supine position for long periods. Although respiratory function in the morbidly obese patient is greatly enhanced with the reverse Trendelenburg position, this position decreases venous pressure and predisposes to deep venous thrombus formation. All patients should make every attempt to walk during the evening after operation and deep venous thrombosis prophylaxis using standard or low-molecular-weight heparin should be administered subcutaneously 30 minutes before the start of the operation and for at least 2 days or until the patient is ambulatory. Intermittent sequential venous compression boots are also useful to counteract the increased venous stasis and the propensity for clotting. It is important to initiate this treatment before induction of anesthesia and throughout the operative procedure. Compression boots are usually part of a standard preoperative protocol in gastric procedures for weight control and should also be used for both elective and emergency procedures on morbidly obese patients.

Patients with severe venous stasis disease, manifested by pretibial stasis ulcers or bronze edema, are at particularly high risk for fatal pulmonary embolism (PE).²³ If mean pulmonary arterial pressure is greater than or equal to 40 mm Hg, consideration should be given to prophylactic insertion of an inferior vena caval filter because of the high risk of a fatal pulmonary embolism in these patients.³³

Jejunioileal Bypass

The first popular surgical procedure for morbid obesity was the jejunioileal bypass. This operation produced an obligatory malabsorption state through bypass of a major portion of the absorptive surface of the small intestine. The procedure connected a short length of proximal jejunum (8 to 14 inches) to the distal ileum (4 to 12 inches) as an end-to-end or end-to-side anastomosis. The end-to-end procedures, which were associated with a better weight loss, required decompression

of the bypassed small intestine into the colon. The jejunioileal bypass was associated with a number of early and late complications. The most serious postoperative complication was cirrhosis due to either protein-calorie malnutrition or absorption of degradation products from bacterial overgrowth in the bypassed intestine. Other complications include cholelithiasis, urolithiasis, metabolic acidosis, chronic diarrhea with electrolyte depletion, iron deficiency anemia, and vitamin K deficiency resulting from bacterial overgrowth.²⁴ Randomized prospective studies have shown that the gastric bypass operation is associated with a comparable weight loss and a significantly lower complication rate than jejunioileal bypass.²⁵ Because of the significant complication rate, standard jejunioileal bypass should no longer be performed.

Gastric Procedures for Morbid Obesity

In 1969, investigators reported the results of weight loss after division of the stomach into a small upper pouch connected to a loop gastroenterostomy. The concept for this procedure was based on the observation of weight loss that sometimes followed subtotal gastrectomy for duodenal ulcer disease. There was initial concern that peptic ulcers would develop in the bypassed stomach or duodenum, and although these have occurred, the incidence is low. The technique for gastric bypass was simplified with the use of stapling instruments. The concept of gastroplasty was then proposed as a safer, easier method for restricting food intake. In gastroplasty, the stomach is only stapled and not divided, leaving a small opening to permit the normal passage of food into the distal stomach and duodenum. Thus, weight loss can be assisted through pure restrictive gastric procedures (gastroplasty or gastric banding) or a combination of restriction and malabsorption (gastric bypass, biliopancreatic diversion).

Gastroplasty

- 6 Gastroplasties are purely restrictive procedures that have been performed with either horizontal or vertical placement of the staples. Horizontal gastroplasty usually requires ligation and division of the short gastric vessels between the stomach and spleen, and it carries the risk of devascularization of the gastric pouch or splenic injury. The failure rate (loss of <40% of excess weight) of horizontal gastroplasty ranges from 42% to 71%.²⁶ The vertical banded gastroplasty is a procedure in which a stapled opening is made in the stomach with a circular stapler 5 cm from the cardioesophageal junction. Two applications of a 90-mm stapling device are made between this opening and the angle of His, and a 1.5 × 5-cm strip of polypropylene mesh is wrapped around the stoma on the lesser curvature and sutured to itself but not to the stomach. Erosion of the mesh into the stomach has been an unusual complication of this procedure. Pouch enlargement and stomal dilation are less common with the vertical technique, although staple line disruption occurs in up to 35% of cases. Some surgeons now recommend transecting the stomach to decrease the incidence of this complication.

Gastric Bypass

- 7 Gastric bypass combines restriction and malabsorption to assist weight loss. A small (15- to 30-mL) gastric pouch is created along the lesser curve with staplers, followed by construction of a gastrojejunostomy (most commonly Roux-en-Y configuration) with a 1-cm stoma to drain the pouch. With the Roux technique, a 40- to 50-cm jejunal limb provides moderate malabsorption and limits bile reflux (Fig. 45.1). Significantly improved weight loss has been achieved in the superobese

FIGURE 45.1. Open proximal Roux-en-Y gastric bypass.

population (BMI ≥ 50 kg/m²) with a 150-cm Roux limb (long-limb gastric bypass).²⁷

Gastroplasty Versus Gastric Bypass

Roux-en-Y gastric bypass provides significantly improved weight loss over vertical banded gastroplasty. Reduction in excess body weight at 2 years ranges from 60% to 70% with gastric bypass compared with 40% to 50% with vertical banded gastroplasty. Gastric bypass carries a higher incidence of stomal ulcer, stomal stenosis, vitamin B₁₂ deficiency, and, in menstruating women, iron deficiency anemia than does gastroplasty. Gastric bypass is, however, more effective than vertical banded gastroplasty in correcting glucose intolerance in patients without overt type 2 diabetes mellitus. “Sweet eaters” tend to achieve greater weight reduction with gastric bypass, likely from the development of dumping syndrome symptoms.²⁸

Weight reduction failures nonetheless occur with gastric bypass. Although regained weight could be the result of staple disruption, pouch expansion, or stomal dilation, these findings are not observed in the majority of patients. Approximately 10% to 15% regain lost weight or fail to achieve an acceptable weight loss. The cause for this failure appears to be excessive, constant nibbling on foods with high caloric density.

Partial Biliopancreatic Diversion

The partial biliopancreatic diversion was developed as both a gastric restrictive procedure and a malabsorptive procedure that does not have a blind intestinal limb for bacterial overgrowth.³⁴ In this operation (Fig. 45.2), the quantity of food ingested is partially restricted and then passes down the intestine mostly undigested and unabsorbed until it reaches the bile and pancreatic juices, 0.5 meter from the ileocecal valve, where digestion and absorption take place. Treated patients usually pass four to six stools per day, which are foul smelling

FIGURE 45.2. Biliopancreatic diversion. A distal gastrectomy is performed, followed by division of the distal small bowel 250 cm proximal to the ileocecal valve. The proximal bypassed bowel is anastomosed to the ileum 50 cm from the ileocecal valve.

and float, reflecting malabsorption of fat. Reduction in excess weight approximates 70% to 80%.

As with the proximal or standard gastric bypass, patients with the biliopancreatic diversion are at risk for iron deficiency anemia and vitamin B₁₂ deficiency. In addition, they are at risk for protein deficiency, osteoporosis secondary to calcium and vitamin D malabsorption, night blindness and skin eruptions secondary to vitamin A deficiency, and problems with the other fat-soluble vitamins, E and K.³⁴ Italian patients—the operation was developed in Italy—appear to have less malabsorption and nutritional deficiencies than U.S. patients, probably because of a much lower fat content in the Italian diet. The duodenal switch operation is a modification of the partial biliopancreatic bypass but still may be associated with malnutrition and fat-soluble vitamin and calcium deficiencies.³⁵

Laparoscopic Obesity Surgery

The adjustable silicone gastric band has been developed to be placed laparoscopically. The procedure involves placing the band around the proximal stomach to create a 15-mL pouch (Fig. 45.3). The amount of restriction is adjusted by injecting saline into a subcutaneously implanted port. This procedure has become very popular in Europe, where loss of up to 50% of excess weight at 2 years has been reported. This device was approved by the U.S. Food and Drug Administration in 2001, but American trials have yielded varied results.^{36,37} Long-term studies validating its safety and efficacy are needed. Complications include band slippage, gastric obstruction, port malfunction or infection, and band erosion.

Laparoscopic Roux-en-Y gastric bypass is being performed with increasing frequency in the United States. This is a tech-

FIGURE 45.3. Schematic representing laparoscopic adjustable gastric banding. The buckle would be oriented medially, and anterior gastrogastric sutures would be placed proximal and distal to the band to prevent gastric herniation.

nically demanding procedure with a steep learning curve. Five or six ports are utilized (Fig. 45.4). A linear cutting stapler is used to create a stapled side-to-side jejunojunctionostomy after measuring a 50-cm Roux limb. This alimentary limb can be tunneled through the mesocolon (retrocolic) or allowed to pass anterior to the colon and stomach (antecolic). The proximal lesser curvature 15- to 20-mL gastric pouch is created with the linear cutting stapler with care to avoid injury to the spleen or esophagus. The gastrojejunostomy is formed with a stapled posterior row and a hand-sewn anterior row (Fig. 45.5). The anastomosis is tested with insufflation via a gastro-scope. Drainage and postoperative radiographs to assess for

FIGURE 45.5. Laparoscopic proximal Roux-en-Y gastric bypass (retrocolic, retrogastric).

leaks can be performed routinely or selectively according to surgeon preference.

Although the laparoscopic technique is associated with increases in operative time, operative cost, and incidence of gastrojejunal stricture, advantages include decreased hospital length of stay, decreased incidence of wound infection and incisional hernia, and reductions in perioperative blood transfusions. Internal hernias may increase in frequency with the laparoscopic technique as a result of decreased severity of adhesions (Fig. 45.6). In terms of weight loss, laparoscopic

gastric bypass offers similar short-term reductions in excess body weight when compared with the open technique in randomized prospective trials.³⁸

COMPLICATIONS OF GASTRIC SURGERY FOR MORBID OBESITY

The most feared complication of gastric surgery for morbid obesity is gastrointestinal leak (Algorithm 45.1). This occurs most commonly at the gastrojejunostomy, although other potential sites include the jejunojejunostomy, excluded stomach, and inadvertent enterotomies. Following gastric bypass,

ALGORITHM 45.1

ALGORITHM 45.1. Management of anastomotic leak after gastric surgery for obesity.

the excluded stomach can perforate because of marked dilation resulting from biliopancreatic limb obstruction. This complication is often heralded by frequent hiccups and can be diagnosed by noting a large gastric bubble on abdominal radiographs. Impending gastric perforation requires urgent percutaneous or operative decompression. In patients undergoing revisional gastric surgery for obesity, a gastrostomy tube should be inserted prophylactically for decompression.

Leaks can be extremely difficult to detect in the morbidly obese patient. If patients complain of increasing pain in the abdomen, back, or shoulder (consistent with irritation of the left hemidiaphragm) or of pelvic pressure or hiccups, the clinician must suspect a leak. Tachycardia, tachypnea, fever, anxiety, and leukocytosis are often present, although it is not uncommon for a leak to manifest as unexplained persistent tachycardia in an asymptomatic patient. This complication can often be confirmed with an emergent upper gastrointestinal series using water-soluble contrast. If the study is negative but suspicion is high, the patient's abdomen should be reexplored urgently. An attempt to repair the leak should be made, and a large sump drain should be placed nearby because the repair frequently breaks down. This leads to a controlled fistula, which usually heals with total parenteral nutrition or tube feeds via gastrostomy or jejunostomy. Some gastrojejunal leaks can be managed nonoperatively in situations where the leak is drained (via a drain placed at the time of operation or radiographically guided) or contained; in either circumstance, Algorithm 45.1 is appropriate only in stable patients without signs of systemic toxicity. Factors associated with leak include increasing age, revisional surgery, male gender, and sleep apnea.³⁹

Marginal ulcers develop in approximately 10% of patients with gastric bypass even when treated with postoperative acid suppression. This complication usually responds to additional medical therapy with proton pump inhibitors. Stomal stenosis can occur following gastric bypass or vertical banded gastroplasty. Outpatient endoscopic dilatation is usually successful in patients with gastric bypass, although more than one treatment may be necessary.

Rapid weight loss following bariatric surgery is associated with a high incidence (up to 35%) of gallstone formation and need for subsequent cholecystectomy for biliary colic or acute cholecystitis. Some surgeons recommend prophylactic cholecystectomy at the time of bariatric surgery, whereas others perform cholecystectomy only if sonographic evidence of gallstones is identified. Ursodeoxycholic acid (300 mg orally twice daily) administered for 6 months following gastric bypass (the period of rapid weight loss) reduces the risk of gallstone formation to 2%.⁴⁰ Compliance with this medication can be difficult secondary to adverse side effects (nausea, diarrhea, and pruritus).

Nutritional follow-up is mandatory after gastric bypass because these patients are at risk for deficiency states and their sequelae. Vitamin B₁₂, iron, and calcium supplements are often necessary along with routine administration of multivitamins. A high-protein diet (50 g/d for women and 65 g/d for men) is required to avoid protein malnutrition.

The incidence of perioperative venous thrombosis and pulmonary embolism can be reduced with prophylactic subcutaneous heparin, sequential compression boots, and early ambulation. Pulmonary embolism nonetheless occurs in 0.9% of patients despite these measures; independent risk factors include extreme obesity (BMI of 50 kg/m² or greater), obesity hypoventilation syndrome, and venous stasis. It has been recommended that prophylactic vena caval filters be placed in these high-risk patients at the time of obesity surgery.

The operative mortality rate after gastric surgery is now approximately 0.5% in most series. Independent risk factors associated with increased risk of death include gastrointestinal leak, pulmonary embolus, hypertension, and preoperative weight.⁴¹

FAILED GASTRIC SURGERY FOR OBESITY

Revision of a failed gastroplasty is often unsuccessful because of recurrence of stomal dilation and problems with gastric emptying; conversion to gastric bypass provides better results. Laparoscopic gastric banding with ineffective weight loss can likewise be converted to gastric bypass, but the complication rate with this and any revision is higher than for a primary gastric bypass. Revision of a dilated gastrojejunal stoma has not been effective, but application of an adjustable band to the pouch above the stoma has been suggested as an option for this problem. Most patients who fail a gastric bypass do so as a result of dietary indiscretion. If a patient has significant obesity-related comorbidities that have failed to resolve or have returned with weight gain, conversion to long-limb gastric bypass can be performed. This modification can be associated with steatorrhea, fat-soluble vitamin deficiency, and osteoporosis.

OVERVIEW OF GASTRIC SURGERY

Gastric procedures for morbid obesity can yield a satisfactory weight reduction, with an average loss of two thirds of excess weight within 1 to 1.5 years. Weight becomes stable at this level in most patients as the reduced caloric intake meets caloric expenditure. The patients must be followed carefully to ensure adequate protein, vitamin, and other micronutrient levels.

Numerous comorbidities associated with morbid obesity resolve following gastric bypass (Table 45.5). Weight loss completely corrects type 2 diabetes mellitus in three fourths of cases, hypertension in two thirds of patients, and headaches associated with cerebrospinal fluid pressure elevation in almost all patients with pseudotumor cerebri. OSA resolves with weight loss in approximately 80% of cases. Hypoxemia and hypercarbia seen in OHS return toward normal with weight reduction.⁴² Elevated pulmonary artery and pulmonary capillary wedge pressures also improve significantly after weight loss with correction of abnormal arterial blood gases. The loss of weight usually corrects female sexual hormone abnormalities, permits healing of chronic venous stasis ulcers associated with venous insufficiency, prevents reflux esophagitis, relieves stress overflow urinary incontinence, and improves low back pain as well as joint-related pain. Weight loss can

TABLE 45.5 **RESULTS**

RESOLUTION OF COMORBIDITIES FOLLOWING GASTRIC BYPASS

COMORBIDITY	RESOLUTION RATE (%)
Diabetes	73
Obstructive sleep apnea (mild/moderate)	100
Obstructive sleep apnea (severe)	75
Hypertension (high blood pressure)	56
Urinary stress incontinence	91
Gastroesophageal reflux disease	90
Venous stasis ulcers	94
Pseudotumor cerebri	100
Joint pain	71

permit successful total artificial joint replacement. Patient self-image is often markedly improved after gastric surgery for obesity.

Treatment of morbidly obese patients requires a multidisciplinary approach including psychologists, nutritionists, and experienced physicians and ward personnel. Patients must be willing to make a lifelong commitment to behavioral modification, regular exercise, and long-term medical follow-up.

CHAPTER 46 ■ GASTRIC NEOPLASMS

REBECCA M. MINTER

KEY POINTS

- 1 The presence of a gastric adenomatous polyp is a marker of increased risk for the development of cancer in the remaining gastric mucosa, and therefore these patients should be enrolled in an appropriate endoscopic surveillance program.
- 2 *Helicobacter pylori* infection is the predominant risk factor for gastric carcinogenesis; however, additional cofactors also play an important role and likely drive the progression from a premalignant condition to adenocarcinoma in most individuals.
- 3 The symptoms produced by gastric cancer are not specific and can mimic those associated with several nonneoplastic gastroduodenal diseases, especially benign gastric ulcer.
- 4 The extent of gastric resection is determined by the need to obtain a resection margin free of microscopic disease, and a minimum of 15 nodes are required for adequate nodal sampling and staging.
- 5 Multimodality treatment should be the standard of care for treating locally advanced resectable gastric cancer.
- 6 Low-grade gastric MALT lymphomas are usually effectively treated with eradication of *H. pylori* infection alone.
- 7 Almost all (95%–99%) gastrointestinal stromal tumors express the KIT antigen.

Gastric cancer is a relatively common, frequently lethal affliction and remains a serious and unsolved problem in general surgery. The disease often is not recognized until it is at an advanced stage. Gastric cancer usually cannot be controlled by surgery alone, and surgical cure rates have remained disappointingly low. Increasingly, a multidisciplinary approach is being applied to these difficult neoplasms, with some modest improvements in outcome finally being observed. Technical innovations and basic scientific investigations continue to be applied to this disease, and cautious optimism for the future is appropriate.

ADENOCARCINOMA

Epidemiology

Starting in 1930, the incidence of gastric cancer declined dramatically in the United States (Fig. 46.1). By 1980, the incidence of gastric cancer (10 cases per 100,000 population) was approximately one fourth the incidence recorded in 1930. The incidence of the disease remained relatively constant in the decades from 1980 to 2000.¹ By 1997, reported new cases of gastric cancer had declined to 22,000. While this is a small number relative to the 150,000 estimated deaths from cancer of the lung,² gastric cancer remains among the top 10 causes of cancer-related deaths for both men and women in the United States. In 2008, it is estimated that 21,500 new cases of gastric cancer will be diagnosed in the United States—thus the incidence remains fairly stable over the last decade.³ An increase in the proportion of proximal gastric cancers has been observed, with young white men being much more likely to present with proximal gastric cancers whereas distal cancers are more likely to occur in Asian, African American, and Hispanic patients.⁴ While the reasons for the decline in the incidence of gastric cancer in the 1930s are not entirely known (though some attribute the decreased incidence to the introduction of refrigeration and widespread access to fresh fruits and vegetables), we now have a better understanding of the factors contributing to its persistence.

The worldwide incidence and death rates for gastric cancer vary markedly. The highest age-adjusted death rate for gastric cancer occurs in Japan, where the disease accounts for approximately 50% of cancer-related deaths in men and 40% of cancer deaths in women. High incidence rates are also reported in South Korea, Chile, Costa Rica, Hungary, Portugal, Singapore, and Romania, a geographically and ethnically diverse group. It had been widely assumed that exposure to environmental carcinogens accounted for the increased disease frequency observed in these populations. A high intake of salt and nitrite-containing preserved foods and a relative lack of fresh fruits and vegetables have been implicated. The supposition that environmental carcinogens play a role in gastric carcinogenesis is supported by studies of immigrant populations; migration from an area at high risk to one at low risk is associated with a decreased probability of developing gastric cancer. The predominant risk factor for gastric carcinogenesis is now generally regarded as infection with the organism *Helicobacter pylori*.

Premalignant Lesions. The risk for development of gastric cancer is greater in stomachs that harbor polyps. Risk is related most closely to polyp histologic type, size, and number. Variations in these three factors account for the wide range in reported risk associated with gastric polyps. In terms of malignant potential, gastric polyps can be divided into two broad categories—hyperplastic polyps and adenomatous polyps.

Hyperplastic polyps are common, occurring in 0.5% to 1% of the general population and accounting for 70% to 80% of all gastric polyps. The hyperplastic polyp contains an overgrowth of histologically normal-appearing gastric epithelium. Atypia is rare. Hyperplastic gastric polyps are considered to have no neoplastic potential. Most people with hyperplastic polyps are asymptomatic. Dyspepsia and vague epigastric discomfort are the most common complaints, although coexistent gastroduodenal disease is also frequently identified. Complications are unusual, and gastrointestinal hemorrhage occurs in less than 20% of patients. When hyperplastic polyps are discovered, endoscopic removal for histologic examination is indicated and is sufficient treatment. Subsequent surveillance is also not necessary given the lack of neoplastic potential in these polyps.

FIGURE 46.1. Incidence of gastric cancer deaths in the United States.

1 Adenomatous polyps, in contrast, have a distinct risk for the development of malignancy.⁵ Mucosal atypia is frequent, and mitotic figures are more common than in hyperplastic polyps. Dysplasia and carcinoma in situ have developed in adenomatous polyps observed over time. The risk for the development of carcinoma has been estimated at 10% to 20% and is greatest for polyps more than 2 cm in diameter. Multiple adenomatous polyps increase the risk of cancer. The presence of an adenomatous polyp is also a marker indicating an increased risk for the development of cancer in the remainder of the gastric mucosa.

Symptoms are similar to those for hyperplastic polyps. Endoscopic removal is indicated for pedunculated lesions and is sufficient if the polyp is completely removed and shows no evidence of invasive cancer on histologic examination. Operative excision is recommended for sessile lesions larger than 2 cm, for polyps with biopsy-proved invasive carcinoma, and for polyps complicated by pain or bleeding. After removal, endoscopic surveillance of the remaining gastric mucosa is indicated.

Gastritis. The incidence of both gastric cancer and atrophic gastritis increases with age. Chronic gastritis is frequently associated with intestinal metaplasia and mucosal dysplasia, and these histologic features are often observed in mucosa adjacent to gastric cancer. Gastritis is frequently progressive and severe in the gastric mucosa of patients with cancer.

Gastric malignancy seems to be increased in patients with chronic gastritis associated with pernicious anemia, although the risk appears to have been overstated in the past. This disease, characterized by fundic mucosal atrophy, loss of parietal and chief cells, hypochlorhydria, and hypergastrinemia, is

present in 3% of people older than 60 years. For people in whom pernicious anemia has been active for more than 5 years, the risk of gastric cancer is twice that of age-matched control subjects. Evidence also indicates an increased risk of gastric carcinoid development in patients with pernicious anemia. This increased risk warrants aggressive investigation of new symptoms in patients with long-standing pernicious anemia, but it is not high enough to justify repeated endoscopic surveillance.

Intestinal metaplasia, the presence of intestinal glands within the gastric mucosa, is also commonly associated with both gastritis and gastric cancer. The evolution from metaplasia to dysplasia to carcinoma to invasive cancer has been demonstrated in other organs and in adenocarcinoma arising in the gastroesophageal junction. However, no direct evidence can be provided for this progression in gastric cancer.

2 *Helicobacter Pylori.* As outlined earlier, *Helicobacter pylori* has been unequivocally associated with chronic inflammatory conditions in the stomach, and this association has stimulated interest in the role of chronic infection by this organism in gastric carcinogenesis. Childhood acquisition of *H. pylori* infection is frequent in areas of high gastric cancer incidence, and high rates of infection have been identified in patients with premalignant lesions and invasive cancer.

In the United States, seropositivity for *H. pylori* increases the risk for cancer development approximately threefold.⁶ Infection with *H. pylori* is associated with an increased risk of adenocarcinoma of both major histologic types and for tumors arising in the body or antrum of the stomach. In contrast, *H. pylori* infection is not a risk factor for cancers of the gastroesophageal junction, which are frequently associated with mucosal abnormalities of Barrett esophagus and which seem to follow the metaplasia to dysplasia to carcinoma pattern of development.

The presumed mechanism of carcinogenesis related to *H. pylori* infection stems from the known association between chronic atrophic gastritis and inflammation, and the subsequent development of gastric adenocarcinoma. Despite this known association, *H. pylori* cannot solely account for gastric carcinogenesis. For patients chronically infected with *H. pylori*, only about 1% will develop the gastric cancer phenotype, which consists of corpus-predominant gastritis, multifocal atrophic gastritis, high gastrin levels, hypochlorhydria/achlorhydria, and low pepsinogen I/II ratio. Most subjects infected with *H. pylori* will develop the simple gastritis phenotype that is not associated with any significant clinical outcome, or the duodenal ulcer phenotype (10%–15% of infected subjects), which consists of antral predominant gastritis, high gastrin and acid secretion, and actually provides protection from developing gastric cancer.⁷ There is variable distribution of these three phenotypes geographically, with particular prevalence of the gastric cancer phenotype in certain parts of Asia where gastric cancer is common.⁸ Currently worldwide it is estimated that approximately 50% to 75% of the mortality from gastric cancer is attributable to *H. pylori* infection.⁹ Other cofactors such as bacterial virulence factors, environmental exposures, and host genetic factors also clearly play an important role in the pathogenesis of gastric carcinogenesis following infection-related gastritis.^{7,10}

Previous Gastric Surgery. Several uncontrolled reports have suggested that gastric cancer is more likely to develop in people who have undergone previous partial gastrectomy, with patients who have undergone a gastrojejunal (Billroth II) anastomosis seeming to be at higher risk for carcinogenesis than those reconstructed with a gastroduodenal anastomosis (Billroth I).^{11,12} The so-called *gastric remnant cancer* is a true clinical entity, although the risk for development of this gastric neoplasm appears to have been overestimated. Several large, prospective studies with long-term follow-up indicate that the

relative risk is not increased for up to 15 years after gastric resection, likely due to surgical removal of mucosa at risk for development of gastric cancer, followed by modest increases in cancer risk (three times the control value) observed only after 25 years.¹³⁻¹⁶

The cellular mechanisms that contribute to the development of neoplasia in the remnant stomach are unknown. Decreased luminal pH, bacterial overgrowth with increased production of *N*-nitroso carcinogens, and reflux of bile acids into the stomach have been postulated to promote cancer development, but remain unproved. Vagotomy, often performed in conjunction with gastric surgery for benign disease, does not appear to promote cancer development. A population-based study from Sweden of 7,198 vagotomized patients followed for up to 18 years did not report increased risk.¹⁴

A recent study explored genetic alterations in gastric remnant cancer and found that the microsatellite instability high (MSI-H) phenotype frequency was much higher (43%) in gastric remnant cancers than in sporadic gastric cancers (6%), and that this incidence was much higher in patients who had undergone a Billroth II anastomosis (67%) as compared to those who had undergone a Billroth I anastomosis (11%). Additionally, these MSI-H phenotype tumors were significantly associated with a lack of expression of hMLH1 and hMSH2—two important DNA mismatch repair genes. The significance of this relationship is not yet clear; however, it is postulated that this unfavorable phenotype may account in part for the poor prognosis associated with these tumors.¹⁷ Reported 5-year survival ranges from 7% to 33% for gastric remnant cancers, though this poor prognosis is most likely due to the fact that these cancers are usually diagnosed at an advanced stage when treatment options are limited.

Clinical Features

- 3 The symptoms produced by gastric cancer are not specific and unfortunately can closely mimic those associated with a number of nonneoplastic gastroduodenal diseases, especially benign gastric ulcer (Fig. 46.2). In early gastric cancers, epigastric pain is present in over 70% of patients.¹⁸ The pain is often constant, nonradiating, and unrelieved by food ingestion. In a surprising number of patients, pain can be relieved, at least temporarily, by antacids or gastric antisecretory drugs. Anorexia, nausea, and weight loss are present in less than 50% of patients with early gastric cancers but become increasingly common with disease progression. Dysphagia is present in

FIGURE 46.2. Clinical symptom frequency in benign gastric ulcer, early gastric cancer, and advanced gastric cancer. (Adapted with permission from Meyer WC, Damiano RJ, Postlethwait RW, et al. Adenocarcinoma of the stomach: changing patterns over the past four decades. *Ann Surg* 1987;205:18.)

Pain	Cachexia
Nausea and vomiting	Abdominal mass
Anorexia	Abdominal tenderness
Dysphagia	Hepatomegaly
Melena	—

20% of patients with proximal gastric lesions. Overt gastrointestinal hemorrhage is present in only 5%. Perforation is rare (1%).

In most patients with early gastric cancers, physical examination is negative. Stool is guaiac positive in one third. Abnormal physical findings usually reflect advanced disease (Table 46.1). Cachexia, abdominal mass, hepatomegaly, and supraclavicular adenopathy usually indicate metastatic disease.¹⁹ There are no simple laboratory tests specific for gastric neoplasms.

Diagnosis and Screening

Fiberoptic endoscopy is the most definitive diagnostic method when gastric neoplasm is suspected. In the initial stages, gastric cancers can appear polypoid, as flat, plaque-like lesions, or as shallow ulcers. Advanced lesions are typically ulcerated. The ulcer border can have an irregular, beaded appearance because of infiltrating cancer cells, and the base is frequently necrotic and shaggy. The ulcer can appear to arise from an underlying mass. Although each of these features suggests a malignant ulcer, differentiation of benign from malignant gastric ulcers can be made definitively only with gastric biopsy. Accuracy of diagnosis can exceed 95% if multiple biopsy specimens are obtained. False-negative results occur in approximately 10% of patients, usually as the result of sampling error or due to the absence of a mucosal abnormality as can occur with linitis plastica; false-positive results are rare. Diagnostic accuracy can be further enhanced by the addition of direct brush cytology and with the use of endoscopic ultrasound with fine-needle aspiration biopsy for infiltrative tumors involving the wall of the stomach without obvious mucosal abnormalities.

The ability to diagnose gastric adenocarcinoma endoscopically has prompted screening programs for populations at high risk. Mass screening has been performed in Japan since the 1960s with the use of fiberoptic endoscopy. The overall yield for the Japanese screening program has been 0.12%,²⁰ and has decreased the gastric cancer mortality by two thirds in compliant patients.⁹ The proportion of early cancers identified (defined as tumors whose growth is confined to the mucosa and submucosa regardless of the presence or absence of metastatic disease in the perigastric lymph nodes) steadily increased during the study period. Currently, greater than 60% of gastric malignancies detected by this program are early cancers, and early detection has translated directly into improved survival (Fig. 46.3). The Japanese findings that early detection and identification of early gastric cancer can improve survival has been confirmed by European investigations, in which patients with early gastric cancers have been shown to have survival rates equivalent to those of patients with benign gastric ulcer¹⁸ (Fig. 46.4). Despite the success of the Japanese

FIGURE 46.3. Early cancer survival rate in Japan.

screening program, mass screening for gastric adenocarcinoma has not been advocated in the United States or Canada. With incidence rates approximately one fifth of those observed in Japan, detection rates are too low to justify such a program economically. It will be interesting to observe over time whether the Japanese screening program continues to be cost

FIGURE 46.4. Early cancer survival rate in Europe.

FIGURE 46.5. Barium contrast radiograph demonstrating extensive involvement of the gastric body by infiltrating adenocarcinoma (linitis plastica). The gastric silhouette is narrowed (arrows), and the stomach is nondistensible.

effective given the significant decrease in the rate of chronic *H. pylori* infection in persons now under the age of 30 in Japan (25% vs. 60% as compared to their parents).⁹

Barium contrast radiographs have, in the past, been the standard method for diagnosing gastric neoplasm. Single-contrast examinations have a diagnostic accuracy of 80%. This diagnostic yield increases to approximately 90% when double-contrast (air and barium) techniques are used. Typical findings include ulceration, the presence of a gastric mass, loss of mucosal detail, and distortion of the gastric silhouette (Fig. 46.5). Contrast radiography has been largely supplanted by endoscopy because of the ability to obtain biopsy material by the latter technique.

Computed tomography (CT) has been used both as a primary diagnostic method and to assess for extragastric spread of disease. When performed with intraluminal and intravenous contrast, CT can reliably demonstrate infiltration of the gastric wall by tumor, gastric ulceration, and the presence of hepatic metastases (Figs. 46.6 and 46.7). The technique is less reliable with regard to invasion of adjacent organs or the presence of lymphatic metastases. In most series, involvement of adjacent organs has been overestimated by CT scanning (false-positive). Conversely, metastases to regional or distant lymph nodes have been underestimated (false-negative). One review estimated a 40% to 50% accuracy rate in preoperative local staging of gastric carcinoma for CT scanning.²¹

Endoscopically directed ultrasound is another useful method of preoperative evaluation for local staging and diagnosis. Endoscopic ultrasound (EUS) is excellent at delineating subepithelial lesions that may be confused with gastric cancer, and to guide biopsy of submucosal tumors within the wall of the stomach. Investigation of submucosal masses, infiltrative gastric disorders, enlarged gastric epithelial folds, and differentiation of gastric lymphoma from gastric adenocarcinoma are each aided by endoscopic ultrasound. This technique has the ability to assess the depth and pattern of gastric wall penetration by the tumor as well as relationship to adjacent structures,

FIGURE 46.6. Computed tomography scan demonstrating mass along lesser curvature of the stomach (*black arrow*) and associated lymph node enlargement (*white arrow*).

and has good correlation with intraoperative assessment and histologic findings. Perigastric lymph nodes involved with tumor are also reliably identified by endoscopic ultrasound, and therefore EUS provides the most accurate assessment of local stage of disease (TN status), with an accuracy of 57–83% for staging depth of tumor invasion and 50–78% for nodal involvement.³ Because of a limited depth of tissue penetration, however, endoscopic ultrasound is unable to detect hepatic metastases; this inability is its major limitation in pre-operative staging of patients with gastric cancer. Therefore, EUS serves as an adjunct to cross-sectional methods of radiologic imaging and is only indicated as a staging method for patients with gastric adenocarcinoma who are potentially resectable (e.g. have no evidence of distant metastases on cross-sectional imaging).

Metabolic Imaging

Metabolic imaging with positive emission tomography (PET) using 18 F-fluorodeoxyglucose has been found to be less accurate than cross-sectional imaging and EUS for staging locoregional involvement, but more sensitive for detecting distant metastases in patients with gastric cancer.³ A metaanalysis comparing PET, ultrasound, CT, and magnetic resonance imaging (MRI) found that PET scan was the most sensitive imaging modality for detecting hepatic metastases.²² A separate study found that tumors which responded metabolically on PET to neoadjuvant chemotherapy correlated highly with histopathologic response and improved patient survival.²³ Therefore, current recommendations regarding the use of PET for staging gastric cancer are for selective use for patients with locally advanced tumors where the metastatic potential is high, and in cases where neoadjuvant therapy is being considered.³

Pathology

Gastric adenocarcinoma occurs in two distinct histologic subtypes—intestinal and diffuse. These subtypes are characterized by differing pathologic and clinical features and by differing patterns of metastatic spread.

In the intestinal form of gastric cancer, the malignant cells tend to form glands. The intestinal form of malignancy is more

FIGURE 46.7. Computed tomography scans of the upper abdomen showing extensive thickening of the gastric wall (*black arrows*) caused by infiltrating adenocarcinoma and associated hepatic metastasis (*white arrow*).

frequently associated with gastric mucosal atrophy, chronic atrophic gastritis, intestinal metaplasia, and dysplasia. Gastric cancer with the intestinal histologic subtype is more common in populations at high risk (e.g., Japan), and it occurs with increased frequency in men and older patients. Clinical studies suggest that this subtype more frequently demonstrates blood-borne metastases.

The diffuse form of gastric adenocarcinoma does not demonstrate gland formation and tends to infiltrate tissues as a sheet of loosely adherent cells. Lymphatic invasion is common. Intraperitoneal metastases are frequent. The diffuse form of gastric adenocarcinoma tends to occur in younger patients, in women, and in populations with a relatively low incidence of gastric cancer (e.g., the United States). The prognosis is less favorable for patients with the diffuse histologic subtype.

Efforts have been made to grade tumors on histologic criteria. Progressively anaplastic carcinomas are assigned higher grades. Not surprisingly, histologic grade correlates closely with 5-year survival; only 11% of grade IV patients survive

5 years, whereas 66% of grade I patients are alive 5 years after operation.

Sporadic gastric adenocarcinomas demonstrate a number of chromosomal and genetic abnormalities. Cytometric analysis reveals that gastric tumors with a large fraction of aneuploid cells (with a greater-than-normal amount of nuclear DNA) tend to be more highly infiltrative and have a poorer prognosis. Amplifications of both the *HER-2/neu* and *K-ras* protooncogenes have been consistently detected in gastric ade-

nocarcinomas, and in a small percentage of tumors a lack of expression of the tumor suppressor gene *MKK4* is robustly associated with poor survival.²⁴ The exact mechanisms by which these genetic abnormalities contribute to gastric oncogenesis is currently unclear. Additionally, a number of growth factors, including epidermal growth factor, platelet-derived growth factor, and transforming growth factor- β , are overexpressed in gastric carcinoma cells.²⁵

In the United States the incidence of proximal gastric cancer has been increasing; such that in 2001 the rate of proximal cancers, defined as cancers arising in the cardia and fundus, exceeded that of distal cancers, defined as cancers arising in the antrum and pylorus. Based on this data, collected by the National Cancer Database, proximal cancers are more likely to occur in young white men and distal cancers are more likely to occur in Asian, African American, and Hispanic patients within the United States. The proportion of tumors involving the proximal stomach has dramatically increased over the past decades; in the 1960s, only 16% involved this region, and a clear explanation for this rise in proximal disease remains elusive. In 10% of the cases, the stomach is diffusely involved at the time of diagnosis.¹⁹ Prognosis is distinctly less favorable for tumors arising from the proximal stomach or for those with diffuse involvement of the organ relative to distal tumors, and these patients are much more likely to undergo neoadjuvant and adjuvant therapy.^{4,26} The need to resect other organs in the upper abdomen, in addition to gastric resection, is also an unfavorable prognostic factor,²⁷ and postoperative morbidity increases as more organs are resected in order to achieve negative surgical margins.

The gastric cancer staging format used by the American Joint Committee on Cancer is presented in Table 46.2. The staging system is oriented toward surgical and pathologic examinations but also accurately reflects prognosis (Fig. 46.8). A consideration of staging data illustrates the high frequency with which lymph node metastases are present at the time of diagnosis in the United States, and the severe impact lymphatic involvement has on survival. Even early gastric cancers (tumors restricted to the mucosa and submucosa) have a 15% prevalence of nodal metastasis.

Curative Treatment

Surgical resection is the only hope for cure in gastric cancer, but an advanced stage of disease at the time of diagnosis precludes curative resection for most patients. The surgical objectives in gastric cancer must, therefore, be two: (a) to maximize chances for cure in patients with localized tumor

TABLE 46.2 CLASSIFICATION AND STAGING

TNM CLASSIFICATION FOR STAGING OF GASTRIC ULCER

PRIMARY TUMOR	
TX	Tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ; intraepithelial tumor without invasion of the lamina propria
T1	Tumor invades lamina propria or submucosa
T2a	Tumor invades muscularis propria
T2b	Tumor invades subserosa
T3	Tumor penetrates serosa without invasion of adjacent structures
T4	Tumor invades adjacent structures
REGIONAL LYMPH NODE INVOLVEMENT	
NX	Regional lymph node(s) cannot be assessed
N0	No regional nodal metastasis
N1	Metastasis to 1–6 regional lymph nodes
N2	Metastasis to 7–15 regional lymph nodes
N3	Metastasis in more than 15 regional lymph nodes
DISTANT METASTASIS	
MX	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis

FIGURE 46.8. Survival rates of gastric cancer by stage.

and (b) to provide effective and safe palliation to patients with advanced malignancy. Evolution of the surgical approach to gastric adenocarcinoma has focused on the following six issues: the ability of preoperative tests to detect metastatic disease, the extent of gastric resection needed for potentially curable lesions, the extent of perigastric lymphadenectomy, the adequacy of proximal and distal resection margins, the role of splenectomy, and the implications of involvement of adjacent organs.

Staging Laparoscopy. The ability of CT scanning to detect metastatic disease is limited, especially when tumor deposits are small. The surface of the liver, the omentum, and the peritoneal surfaces are common sites for gastric cancer metastasis that are difficult to evaluate preoperatively by CT scanning. In prospective studies, diagnostic laparoscopy has been superior to preoperative CT or percutaneous ultrasound in detection of peritoneal, hepatic, or lymphatic metastasis. Diagnostic laparoscopy can also be combined with laparoscopic ultrasound to further increase diagnostic yield. Preoperative endoscopic ultrasound and operatively performed laparoscopic ultrasound are complementary techniques. When combined, 100% sensitivity in detecting inoperable cancers has been reported.²⁸

Accurate staging and detection of incurable lesions is crucial because the mean life expectancy of affected patients is only 3 to 9 months. In 10–25% of patients, laparoscopy will detect distant disease that precludes curative resection.^{29–31} Relative to laparotomy, the shorter hospitalization and reduced operative trauma following laparoscopy are obvious benefits to individuals with a short life expectancy. Most patients with systemic metastasis can be treated without the need for palliative surgical resection. In one study, no patients deemed incurable by laparoscopy required subsequent operation.³²

In addition to visual inspection of the abdominal organs and peritoneal surfaces, some have also advocated for the routine use of peritoneal cytological analysis at the time of laparoscopy to further increase the accuracy of staging prior to proceeding with radical surgical resection. A number of retrospective studies have identified positive peritoneal cytology as an indicator of both early recurrence and poor survival. In a recent large series, outcomes for patients with positive peritoneal cytology without gross metastatic disease were not significantly different than for patients found to have gross metastatic disease at the time of laparoscopy,³³ and similar findings have been observed in other smaller series. A current limitation of this approach is that the overall incidence of positive peritoneal cytology in the absence of gross disease is low (6–15%). To try to improve the sensitivity and specificity of this approach, some investigators are exploring the use of advanced diagnostic technologies to identify specific tumor markers on the cells from the peritoneal lavage fluid rather than simply performing cytologic analysis to look for tumor cells.³ Though this staging modality has promise, current recommendations of the National Comprehensive Cancer Network are that additional clinical studies are needed prior to widespread acceptance.³

Laparotomy. Epidemiological studies demonstrate in the United States that gastric cancer has decreased in incidence over the last two decades. Paralleling this decrease in incidence, the frequency of gastric resection for cancer has also declined.³⁴ Using nationwide hospital discharge data, the number of patients with a diagnosis of gastric cancer decreased from 25 cases per 100,000 U. S. adults in 1988 to 20 cases per 100,000 in 2000 (Fig. 46.9). The decreased rate of hospitalization reflected decremental rates of gastric resection, with a 29% decrease from 5.6 cases per 100,000 adults in 1988 to 4.0 cases per 100,000 in 2000 (Fig. 46.9). The overall proportion of hospitalized gastric cancer patients undergoing gastric resection remained constant at 22%.

FIGURE 46.9. Incidence of gastric cancer and gastric cancer resection in the United States, per 100,000 adults, over the time period 1988 through 2000.

Gastric resection for cancer has a relatively high rate of postoperative complications and significant operative mortality. From 1988 to 2000, in-hospital mortality did not significantly change, with an overall mortality rate of 7.4% for the nationwide group. Complication rates were not uniform, however, and varied in relation to hospital experience with gastric surgery. Low-volume centers had an 8.3% mortality rate, medium-volume hospitals had a 7.1% death rate, and high-volume centers had a 6.5% mortality rate (Fig. 46.10). The safety of gastric resection improved progressively from 1988 to 2000 at high-volume medical centers. A decline in mortality was not observed at low- or medium-volume hospitals. Despite no significant change in overall complication rates, patients are spending less time in the hospital after gastric resection (Fig. 46.11). Shorter hospital stays likely reflect improved efficiency with better use of hospital resources, but may also derive from societal efforts to curtail health-care costs.

Since the mid-1990s, the surgical treatment of gastric cancer has continued to evolve, with minimally invasive approaches increasingly pursued for early cancers and increasingly radical operations for advanced tumors. Japanese surgeons have reported the largest experience with early gastric cancer. The Japanese Gastric Cancer Association defines early

FIGURE 46.10. In-hospital mortality as a function of varying hospital volume. Low-volume hospitals are defined as performing four or fewer resections per year. Medium-volume hospitals are defined as performing five to eight resections per year. High-volume hospitals are defined as performing nine or more resections per year.

FIGURE 46.11. Length of stay after gastric resection by time period from 1988 through 2000.

gastric cancer as tumor in which invasion is restricted to the mucosa or submucosa.³⁵ The presence or absence of lymph node metastasis is not considered in this classification. While the presence of lymphatic metastasis cannot be correctly judged by endoscopic findings, it is critically important in prognosis. For tumors confined to the mucosa, lymphatic metastasis is present in 1% to 3% of cases; with submucosal involvement, the rate of nodal positivity increases to 14% to 20%.^{36,37}

For well-differentiated mucosal tumors of less than 3 cm without ulceration, endoscopic mucosal resection has been performed. With this approach, postoperative bleeding or perforation has been reported in 5%, and in 17% histologic examination revealed submucosal invasion that required further operative treatment.³⁸ Reports that suggest underestimation of tumor invasion in 45% and missed lymphatic metastasis in 9% urge caution before widespread acceptance of this technique.³⁹

Laparoscopic gastrectomy has also been reported for treatment of gastric malignancy, with advantages of reduced pain,

shorter hospitalization, and improved quality of life.⁴⁰ Studies from Japan, Korea, and Italy have demonstrated that distal, subtotal, and total gastrectomy with lymphadenectomy are feasible with acceptable morbidity and mortality. However, the majority of patients in these studies had early gastric cancer.³ A multi-center non-randomized study demonstrated acceptable oncologic outcomes following laparoscopic gastrectomy for early gastric cancers in Japan (99% 5-year disease-free survival for Stage I disease and 86% for Stage II disease);⁴¹ however, the non-randomized nature of this study precludes declaration of equivalency of a laparoscopic approach to open surgery due to uncontrolled patient selection bias. A single institution randomized prospective trial for laparoscopic versus open subtotal gastrectomy for distal gastric cancer (in patients with both early and locally advanced gastric cancer) did report equivalent lymph node retrieval (33.4 ± 7.4 in the open group versus 30 ± 14.9 in the laparoscopic group), as well as similar rates of peri-operative morbidity and mortality as outlined in Table 46.3. Five-year overall and disease-free survival were also similar for both groups, 55.7% and 54.8% for the laparoscopic group versus 58.9% and 57.3% for the open group.⁴² However, the lack of a multi-center study design precludes generalizability of this data to all centers, and a true multi-center randomized prospective trial is still needed to truly define the equivalency or superiority of this approach to open surgery.

4 Since the early 1980s, radical operations have been performed for the treatment of gastric cancer, including total gastrectomy, extended subtotal gastrectomy with *en bloc* resection of celiac and splenic lymph nodes, splenectomy, and distal pancreatectomy. With time, it has become apparent that radical operations, in general, increase operative morbidity without improving survival. For early lesions (N0–1, M0) of the antrum or middle stomach, distal subtotal gastrectomy including 80% of the stomach provides satisfactory 5-year survival rates without increasing operative morbidity. Proximal gastric lesions or larger middle stomach lesions may require total gastrectomy or esophagogastrectomy to encompass the tumor (Figs. 46.12 and 46.13). For tumors involving the cardia without involvement of the gastroesophageal junction, some have advocated proximal gastrectomy. While this operation appears to afford equivalent oncologic outcomes compared to total gastrectomy, there is a significantly higher incidence of anastomotic stricture and severe reflux esophagitis with proximal gastrectomy.³ Regardless of the extent of gastric resection, patients with more advanced tumors fare poorly because of the increased likelihood of lymphatic and hematogenous spread.

FIGURE 46.12. Surgical options for resection of gastric neoplasms. **A:** Subtotal gastrectomy with gastrojejununal reconstruction. **B:** Total gastrectomy with esophagojejunostomy. **C:** Esophagogastrectomy with anastomosis in cervical or thoracic position.

FIGURE 46.13. Postoperative radiograph after total gastrectomy with esophagojejunal anastomosis, showing esophagus (E) and jejunum (J).

The extent of gastric resection is determined, in part, by the need to obtain a resection margin free of microscopic disease. Microscopic involvement of the resection margin by tumor cells is associated with poor prognosis.¹⁹ Patients with positive surgical margins are at high risk for development of recurrent disease, and histologically positive margins are strongly correlated with the development of anastomotic recurrence. In the setting of ≥ 5 positive nodes, however, margin positivity does not impact survival.⁴³ In contrast to colon cancer, gastric cancer frequently demonstrates extensive intramural spread. The propensity for intramural metastasis is related, in part, to the extensive anastomosing capillary and lymphatic network in the wall of the stomach. Retrospective studies suggest that when performing a subtotal gastrectomy, a margin of 6 cm from the tumor mass proximally and 3–5.9 cm distally is necessary to ensure a low rate of anastomotic recurrence.⁴⁴ Efforts to achieve even larger margins, however, have not translated into improved survival. Regardless of the type of resection or length of margins, most surgeons obtain a frozen section evaluation of margin prior to proceeding with reconstruction to try to improve the probability that an R0 resection can be achieved.

Radical gastric operations can be performed with acceptable morbidity and low mortality rates in the older age groups at greatest risk for gastric cancer. Mortality rates for total gastrectomy range from 3% to 7%.⁴⁵ Nutritional support in the immediate postoperative period is an important adjunctive measure as patients resume oral intake,⁴⁶ and many surgeons place a jejunal feeding tube at the time of total gastrectomy to ensure that optimal enteral nutrition can be delivered in the post-operative period. Surgical reconstructions that interpose a small intestinal reservoir between the esophagus and the jejunum have been advocated after total gastrectomy, but provide no clear-cut nutritional benefit.^{47–50}

Because gastric cancer metastasizes so frequently to lymph nodes, radical extirpation of draining lymph nodes has both

TABLE 46.4 MANAGEMENT

LYMPHADENECTOMY RESECTIONS IN THE ORIGINAL SYSTEM OF THE JAPANESE RESEARCH SOCIETY FOR GASTRIC CANCER

■ LEVEL	■ DESCRIPTION
R1	Resection of stomach, omentum, and perigastric lymph nodes

therapeutic and staging implications.⁵¹ The value of routine extended lymphadenectomy beyond the peri-gastric lymph nodes in the treatment of gastric adenocarcinoma, however, is controversial. The first favorable experience was reported by Japanese surgeons and the Japanese Research Society for Gastric Cancer.^{52,53} Resections in the original Japanese system are shown in Table 46.4, and the current nomenclature used to define extent of lymphadenectomy is shown in Table 46.5. Only retrospective studies of extended perigastric lymphadenectomy have been reported from Japan. Initial reports suggested an improvement of approximately 10%, stage for stage, for patients with advanced disease treated with R2 or R3 operations.^{52–55} The benefits of extended lymphadenectomy have not been confirmed in non-Japanese centers, and several randomized trials have failed to show a survival benefit for extended lymphadenectomy when the entire patient population was analyzed.^{56–60}

The safety of extended lymphadenectomy is disputed. Data from a national Japanese registry indicate a contemporary mortality of less than 1%.⁶¹ Low mortality risks have been reported from multiinstitutional trials conducted in Italy and Germany.^{60,62} Investigations from the United States, Britain, and the Netherlands have been less optimistic, indicating increased short-term morbidity and in-hospital mortality.^{56,57}

TABLE 46.5 MANAGEMENT

CURRENT NOMENCLATURE USED TO DESCRIBE THE EXTENT OF LYPHADENECTOMY PERFORMED IN CONJUNCTION WITH GASTRECTOMY

■ LEVEL	■ DESCRIPTION
D0	Any lymph node removal that is less than D1
D1	Resection of greater and lesser omenta—which includes the perigastric nodes along the right and left cardiac regions, lesser and greater curves, suprapyloric along the right gastric artery, and infrapyloric
D2	D1 dissection plus the anterior leaf of the transverse mesocolon and all of the nodes along the left gastric artery, common hepatic artery, celiac artery, splenic hilum, and splenic artery
D3	D2 dissection plus the para-aortic lymph nodes

One effect of extended lymphadenectomy appears to be “up-staging” of tumors; as more lymph nodes are removed, additional micrometastatic disease is discovered, and patients are correctly placed in higher-stage categories with worse prognoses.^{63,64} Reciprocally, some patients who do not undergo extended lymphadenectomy will have undetected micrometastases and, because of progressive disease, will decrease the survivorship of the staging group to which they are assigned.

In the United States, greater emphasis has been placed on the total number of nodes removed and histologically examined rather than the location of the nodes (e.g., D1 vs. D2 lymphadenectomy). Current recommendations of the American Joint Committee on Cancer (AJCC) staging for gastric cancer require that a minimum of 15 nodes be evaluated for accurate staging.⁶⁵

Histologically positive lymph nodes are frequently present in the splenic hilum and along the splenic artery, and routine splenectomy has been practiced in some centers. Splenectomy has not been demonstrated to improve outcome for similarly staged patients.^{66,67} Likewise, resection of the tail or body of the pancreas has not been demonstrated to improve survival. Thus, associated splenectomy or pancreateosplenectomy is only beneficial when there is direct extension or bulky adenopathy at the splenic hilum.⁶⁸ Resection of adjacent organs may be required for local control if direct invasion has occurred. In this circumstance, operative morbidity is increased and the long-term survival rate is approximately 25%.⁶⁹

Palliative Treatment

When preoperative evaluation demonstrates disseminated disease, palliation of symptoms becomes a primary consideration. Palliation does not usually require surgery. Obstruction and bleeding can be managed nonoperatively by the use of endoscopic laser fulguration in selected patients. Dysphagia and bleeding caused by proximal lesions can also be controlled in 80% of patients using this modality. Successful application of laser treatment requires adequate visualization, and is hampered by circumferential tumor growth that impedes passage of the endoscope, by sharp angulation of the esophagogastric junction, and by lesions more than 6 cm long.

In the setting of metastatic gastric cancer, palliative resection does not improve survival. Nonetheless, resection appears to provide superior relief of symptoms, particularly dysphagia, as compared with surgical bypass. Bypass of obstructing distal gastric cancers without resection provides relief to less than half of patients, and mean survival is less than 6 months. For proximal obstructing lesions, total gastrectomy with Roux-en-Y esophagojejunum reconstruction may be necessary. An operative mortality rate of less than 5% has been reported, and introduction of stapling devices has reduced the rate of anastomotic leaks to less than 5% in several series. Mean survival after palliative gastric resection approximates 9 months. For symptomatic unresectable gastric adenocarcinoma, radiation therapy with or without concomitant chemotherapy can also provide significant palliation.

- 5 Neoadjuvant and Adjuvant Therapy.** Given the largely disappointing outcomes in Western countries with radical surgery and peri-operative treatment with multiple chemotherapeutic agents for the management of localized gastric cancer, significant interest has been generated for exploring the use of chemoradiation as either a neoadjuvant or adjuvant therapy. Two trials have recently re-defined standard clinical practice for fit patients with resectable locally advanced gastric cancer who can tolerate multi-modality therapy.

The first of these trials was the US Intergroup Trial (SWOG-9008/INT0116), initiated in 1991 to evaluate whether the addition of 5-fluorouracil (5FU), leukovorin, and external beam radiation following gastrectomy would improve survival

over surgery alone for locally advanced gastric cancer. After a median follow-up period of 5 years, disease-free survival and overall survival were significantly improved with multi-modality therapy. Median time to relapse was 30 months in the multi-modality treatment group versus 19 months in the surgery alone group, $p < 0.001$, and overall survival was 36 months in the chemoradiation group versus 27 months in the surgery alone group, $p = 0.005$.⁷⁰ The primary criticism of this trial was that the extent of lymphadenectomy was not standardized, and a less than D1 lymph node dissection was performed in 54% of the patients. Additionally, due to the morbid nature of gastrectomy, approximately one third of the patients were unable to complete their adjuvant chemoradiation due to peri-operative complications or treatment associated toxicities; in fact three patients died related to complications of the chemoradiation therapy. It has been argued that improved radiation techniques and less toxic chemotherapeutic regimens can lessen the toxicity of the therapy; the issue of post-operative disability and diminished tolerance of adjuvant chemoradiation following gastrectomy remains.

More recently, the results of the Medical Research Council Adjuvant Gastric Infusional Chemotherapy (MAGIC) trial were published, which demonstrated a significant survival benefit in patients receiving peri-operative (pre- and post-operative) chemotherapy versus surgery alone for resectable gastric cancer, with a five-year survival rate of 36% versus 23%.⁷¹ Though extent of lymphadenectomy was improved as compared to the US Intergroup trial, only 42% of patients completed all courses of chemotherapy and optimal additional study arms were not evaluated—namely the inclusion of a neoadjuvant chemoradiation treatment arm. Additionally, given the results of the Intergroup trial, it would not be considered standard practice to treat a patient with surgery alone for locally advanced gastric cancer and this was the primary comparison group.

Despite the limitations of these studies, the improved survival observed in both trials makes it clear that a multi-modality approach is superior to surgery alone; patients with locally advanced resectable gastric cancer are optimally treated in a center where a collaborative multi-disciplinary treatment approach can be devised and executed (Algorithm 46.1).

GASTRIC LYMPHOMA

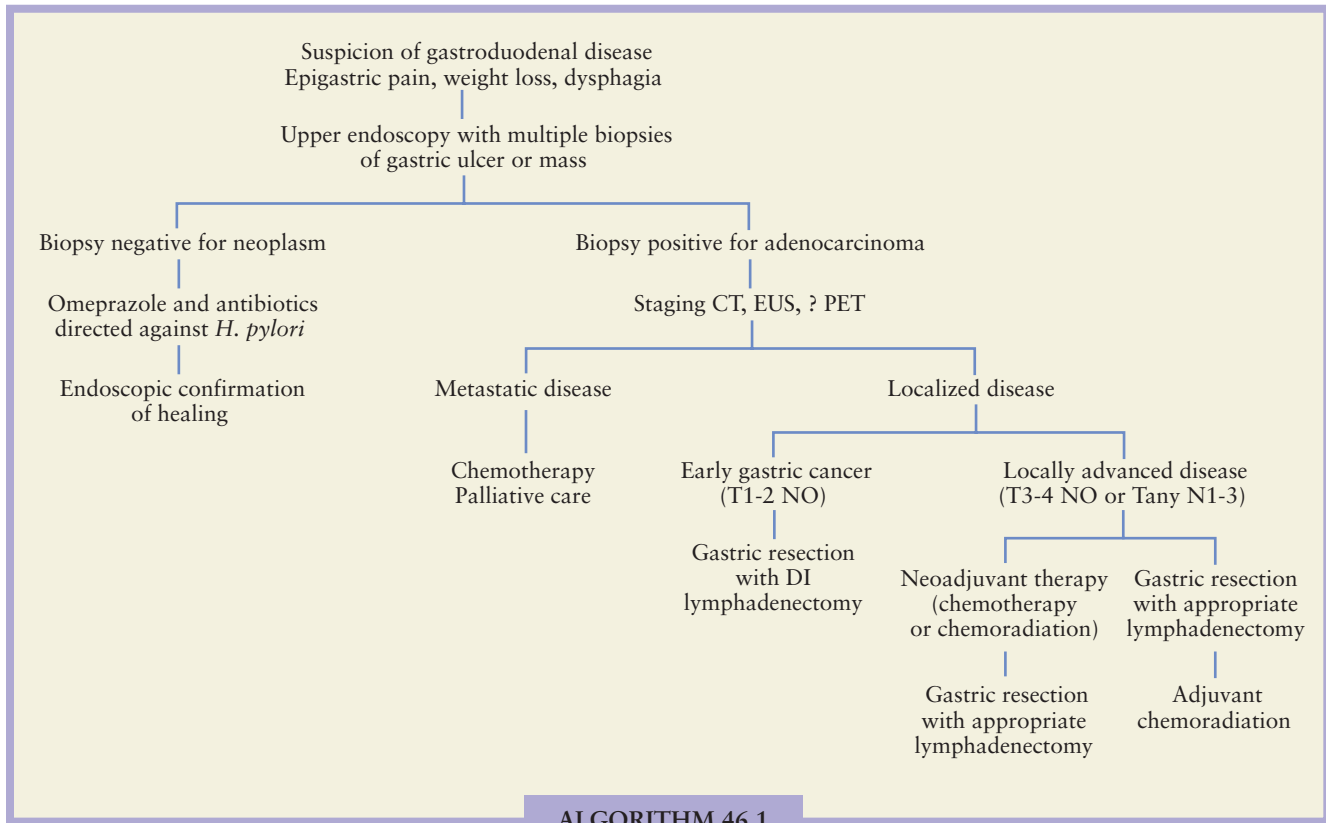

Clinical Features

The stomach is the site of more than half of gastrointestinal lymphomas and is the most common organ involved in extranodal lymphomas. Non-Hodgkin's lymphomas account for approximately 5% of malignant gastric tumors; lymphoma represents an increasing proportion of gastric neoplasms diagnosed currently. Patients are considered to have primary gastric lymphoma if initial symptoms are gastric and the stomach is exclusively or predominantly involved with the tumor. Patients who do not fulfill these criteria are considered to have secondary gastric involvement from systemic lymphoma.

Gastric lymphoma is distinctly uncommon in children and young adults. The peak incidence is in the sixth and seventh decades. Symptoms are indistinguishable from those of gastric adenocarcinoma. Epigastric pain, weight loss, anorexia, nausea, and vomiting are common.⁷² Although gross bleeding is uncommon, occult hemorrhage and anemia are observed in more than half of patients. Patients rarely have spontaneous perforation.

Diagnosis

Radiologic findings are similar to those for adenocarcinoma. Endoscopic examination has become the diagnostic method of

ALGORITHM 46.1. Treatment of gastric adenocarcinoma.

choice. The endoscopic appearance of lesions may be ulcerated, polypoid, or infiltrative. Gastric lymphoma is most commonly localized to the middle or distal stomach and unusually involves the proximal stomach, in contrast to gastric adenocarcinoma. Endoscopic biopsy, combined with endoscopic brush cytology and ultrasonography, provides positive diagnosis in 90% of cases. Submucosal growth without ulceration of the overlying mucosa can occasionally render endoscopic biopsy nondiagnostic. Endoscopic ultrasound-guided biopsy is useful in this circumstance.

When gastric lymphoma is first diagnosed by endoscopic means, evidence of systemic disease should be sought. CT of the chest and abdomen (to detect lymphadenopathy), bone marrow biopsy, and biopsy of enlarged peripheral lymph nodes are all appropriate.

- 6 Mucosa-associated Lymphoma Tissue.** The concept that low-grade gastric lymphomas have features resembling mucosa-associated lymphoid tissue (MALT) is a major advance in the understanding of gastric lymphomas. The gastric submucosa does not ordinarily contain lymphoid tissue, and the development of lymphoid tissue resembling small intestinal Peyer's patches is believed to occur in response to infection with *H. pylori*.⁷³ A number of observations support a causal relationship between chronic *H. pylori* infection and lymphoma development. *H. pylori* is present in the stomachs of more than half of patients with gastric lymphoma.⁷⁴ As with gastric adenocarcinoma, geographic regions with a high prevalence of *H. pylori* also have a high incidence of gastric lymphoma. Infection with *H. pylori* has been noted to precede development of gastric lymphoma.⁷⁵

After development of gastric lymphoid tissue, low-grade lymphoma is postulated to occur as a result of monoclonal B-cell proliferation. Initially, B-cell proliferation depends on

interleukin-2 production by antigenically stimulated nonneoplastic T cells. Progressive genetic rearrangements lead to B-cell proliferation that is independent of *H. pylori*—stimulated interleukin-2. With cumulative genetic defects, low-grade MALT lymphoma progresses to high-grade MALT lymphoma.

Low-grade MALT lymphomas resemble Peyer's patches. Lymphoma cells invade between follicles and into gastric epithelium; invasion of gastric glands forms characteristic lymphoepithelial lesions. Low-grade lesions are often multifocal. Low-grade MALT lesions are less likely than high-grade tumors to invade transmurally, involve perigastric lymph nodes, or invade adjacent organs.⁷⁵ Approximately 40% of gastric lymphomas are low-grade MALT lymphomas.⁷⁶ High-grade MALT lymphomas cannot be distinguished histologically from non-MALT, high-grade B-cell lymphomas.

The concept that low-grade lymphoma depends on continued *H. pylori* antigenic stimulation supports eradication of *H. pylori* with antibiotics as first-line antineoplastic therapy. Complete regression of low-grade MALT lymphomas with antibiotic treatment has been reported in 70% to 100% of cases.^{77,78} The median time to complete response averaged 5 months.⁷⁹ Most patients with partial responses were subsequently determined also to have foci of high-grade lymphoma. Radiation and chemotherapy have been proposed as salvage for antibiotic treatment failures.

Non-MALT Lymphomas. In the past, a multimodality treatment program was used in most centers for primary gastric lymphomas, with gastrectomy as the first step in the therapeutic strategy.⁸⁰ This approach evolved empirically, and prospective data to support it were lacking. Several advantages of this approach had been cited: (a) more accurate histologic evaluation was possible; (b) in cases with localized tumor, the procedure could be curative; and (c) gastrectomy eliminated

FIGURE 46.14. Survival rates of gastric lymphoma by stage.

the risk of life-threatening hemorrhage or perforation which may occur with the treatment of tumors involving the full thickness of the gastric wall.⁸¹ However, the role of gastrectomy for both staging and treatment of gastric lymphoma has diminished significantly; and currently most patients are successfully treated with chemotherapy or chemoradiation therapy alone.

The risk of hemorrhage or perforation which was frequently alluded to in the past as a motive for operative care was overstated, and the incidence of perforation in primary gastric lymphomas that are treated with cytolytic agents in unresected patients approximates only 5%. Endoscopic ultrasonography can be used to detect full-thickness involvement of the gastric wall, and this information can be used to counsel a patient regarding risks of treatment and for decision making regarding risk of perforation.

More than 30% of patients who present with stage II primary gastric lymphoma who undergo apparently adequate surgery and radiation therapy, will develop disease recurrence outside of the treatment field. Patients with stage II primary gastric lymphoma should, therefore, be considered to have systemic disease and to require systemic therapy in addition to surgery or radiation therapy for local management of the primary gastric lymphoma. Survival for gastric lymphoma is closely linked to stage at diagnosis (Fig. 46.14). A recent prospective, randomized study has demonstrated that complication-free survival is highest in patients treated with chemotherapy alone consisting of cyclophosphamide, vincristine, doxorubicin, and prednisone (Fig. 46.15).⁸²

FIGURE 46.15. Actuarial curves of complication-free survival, according to stage.

GASTRIC CARCINOIDS

Gastric carcinoid tumors were previously considered to be very rare tumors; more recent studies have reported that as many as 10–30% of all carcinoids occur in the stomach and they account for at least 1% of all gastric neoplasms.⁸³ Most patients with small gastric carcinoids are asymptomatic and these tumors are most commonly diagnosed incidentally. Occasionally, larger tumors can present with abdominal pain, bleeding, or symptoms related to the secretion of bioactive substances which can be produced by the tumor. When viewed endoscopically at an early stage, carcinoids are reddish-pink to yellow submucosal nodules in the proximal stomach. Endoscopic biopsy is usually diagnostic if deep enough to sample submucosal tumor cells.

Gastric carcinoids arise from enterochromaffin cells which mediate the secretion of histamine, which in turn stimulates parietal cells to secrete acid. Hypergastrinemia is thought to cause enterochromaffin cell hyperplasia, and may lead to the development of gastric carcinoids over time.⁸⁴ Four types of gastric carcinoids have been described. Type I is the most common, and is associated with chronic atrophic gastritis and pernicious anemia. These tumors tend to be slow growing with less malignant potential. Type II tumors are described as having an intermediate malignant potential and occur in patients with Zollinger Ellison syndrome and multiple endocrine neoplasia I. Both Type I and Type II gastric carcinoid tumors are associated with hypergastrinemia. These tumors tend to be small (<1 cm) and are often multi-focal. Type III gastric carcinoids tend to be larger, solitary lesions, are associated with normal gastrin levels, and behave much more aggressively.⁸⁴ Type IV are also larger, solitary, aggressive lesions which are associated with parietal cell hyperplasia. Histologically, the tumors appear as nests of monotonous hyperchromatic cells originating in the submucosa or in the basal area of gastric glands.

A recent review of 1,543 patients with gastric carcinoid identified from the Surveillance Epidemiology and End Results (SEER) database found that the mean tumor size was 1.73 cm, with 12% and 7.9% of patients presenting with lymph node metastasis and distant metastasis, respectively.⁸⁴ Greater depth of tumor invasion and the presence of lymph node or distant metastasis adversely affected survival. Overall, 5-year survival for Types I and II gastric carcinoids is 81% (>95% for Type I lesions), while Type III and IV tumors have only a 33% overall 5-year survival.⁸³ Given the potential for invasion by all gastric carcinoids, attempts at curative resection with appropriate gastric resection and lymphadenectomy is indicated in all patients deemed fit for surgery.

GASTROINTESTINAL STROMAL TUMORS OF THE STOMACH

Gastrointestinal stromal tumors (GIST) were historically misclassified as leiomyomas, leiomyosarcomas, and leiomyoblastomas

due to a mistaken belief that they arose from the smooth muscle in the bowel wall. It is now recognized that GISTs represent a distinct mesenchymal tumor type, and arise from the interstitial cells of Cajal, an intestinal pacemaker cell located in and around the myenteric plexus in the bowel wall. Additionally, 95–99% of GISTs also express the CD117 antigen (*KIT*), and express the *c-kit* receptor. *c-kit* is the receptor for the *KIT* ligand, also known as cytokine stem cell factor. *c-kit* is a tyrosine kinase that acts as a growth factor or developmental antigen receptor; occupation of the receptor acts to stimulate cellular proliferation; positive staining for *c-kit* is diagnostic of a GIST.

While GISTs can arise anywhere within the gastrointestinal tract, approximately 50% of these tumors are found in the stomach. With a slight male predominance, GIST most commonly are identified in individuals in the fourth to eighth decades of life, with a median presentation of approximately 60 years of age. The majority of these tumors are asymptomatic, and are most commonly identified incidentally during endoscopy performed for other reasons. Endoscopically, they typically appear as a submucosal mass. If these tumors become large, they may present with symptoms of abdominal pain and bleeding. GISTs frequently have prominent extraluminal growth patterns, and central necrosis is common as these tumors become large and outgrow their blood supply (Fig. 46.16). If the majority of the growth is extraluminal, endoscopic examination may be unrevealing or only demonstrate umbilication of the mucosa possibly indicate an underlying mass. Endoscopic ultrasound or CT imaging may be helpful for diagnosis in these cases. With large tumors, symptoms related to mass effects with compression of adjacent structures are most common. Additionally, ulceration of the overlying gastric mucosa may occur with tumor necrosis, and these patients may present with significant and intermittent gastrointestinal hemorrhage.

Determination of whether an isolated primary GIST is benign or malignant is difficult, and only the evidence of metastatic disease is diagnostic of a malignant tumor. Certain morphologic features have been identified as being associated with increased risk of local recurrence or distant metastasis. Tumor size (>2 cm) and mitotic index (>5–10 mitoses/high power field) are the most important prognostic variables, as well as site of origin within the gastrointestinal tract; however, all GISTs should be viewed as having malignant potential with the possible exception of very small tumors measuring <1 cm.⁸⁵ As compared to other sites of origin, gastric GISTs tend to have a more favorable prognosis.

If GISTs do metastasize, it is by a hematogenous route (most commonly to peritoneal surfaces and the liver), therefore, associated lymphadenectomy is typically not performed

at the time of gastric resection for GIST. Additionally, unlike adenocarcinoma, GISTs do not present with an intramural growth pattern and thus gross margins of 1–2 cm are deemed adequate for resection of a GIST. Ultimately the goal of resection is a negative microscopic margin. If the tumor involves adjacent structures, then en bloc resection of nonvital structures should be performed whenever possible. Due to the less radical nature of surgery required for appropriate oncologic resection of these tumors as compared to adenocarcinoma of the stomach, minimally invasive surgical techniques have become widely accepted as an appropriate and acceptable operative approach for these tumors.

For patients presenting with metastatic GIST or locally advanced disease, the use of neoadjuvant or palliative targeted molecular therapy should be considered. Imatinib mesylate (Gleevec, Novartis Pharmaceuticals) is a small molecule tyrosine kinase inhibitor which targets *KIT*, and approximately 80% of patients with metastatic GIST will demonstrate at least a partial response to imatinib mesylate therapy. Unfortunately, complete or lasting responses are rare as approximately half of the patients who demonstrate initial responses eventually develop resistance to the drug.⁸⁶ Due to these failures, several second generation tyrosine kinase inhibitors are currently under study for treatment of imatinib-resistant GISTs. The role of imatinib mesylate as a neoadjuvant agent prior to surgical resection for locally advanced tumors is being explored in clinical trials.

CHAPTER 47 ■ ANATOMY AND PHYSIOLOGY OF THE SMALL INTESTINE

ERIC T. KIMCHI, NIRAJ J. GUSANI, AND JUSSUF T. KAIFI

KEY POINTS

- 1 The normal adult anatomy of the small intestine is the result of a complex cascade of embryological events, which results in 270 degrees of total rotation of the bowel around its axis. A failure of these precise steps produces a spectrum of anatomical variants that are grouped together as malrotation of the intestinal tract.
- 2 There is no clear anatomic boundary between the jejunum and ileum. The proximal two fifths of the small intestine distal to the ligament of Treitz has been arbitrarily defined as *jejunum* and the distal three fifths as *ileum*.
- 3 The enteric nervous system contains two major plexuses. The first is the myenteric (Auerbach's) plexus, located between the longitudinal and circular muscle layers.
- 4 The second major plexus of the enteric nervous system is the submucosal (Meissner's) plexus.
- 5 The small intestine is the largest endocrine organ in the human body. The secretion of these numerous hormones and neurotransmitters is specific to distinct anatomic zones within the small intestine.
- 6 The coordination of movements of the gastrointestinal tract is necessary for the proper digestion of food. Well-timed contraction and relaxation patterns are initiated in the gastrointestinal nervous system causing coordinated electrical activity and muscular movements.
- 7 The lumen of the gastrointestinal tract is connected to the outside environment and comes in direct contact with many potentially pathogenic microorganisms. Consequently, the small intestine has a complex defense mechanism to battle against these exposures in different ways.
- 8 The small intestine reabsorbs nearly 80% of the fluid that passes through it. This dynamic process is accomplished by a rapid bidirectional movement of fluid in the intestinal lumen. This ebb and flow of fluid in the intestinal lumen is critical in maintaining normal homeostasis. Minor changes in intestinal permeability or rate of flow of the intestinal contents can result in net secretion and diarrheal states.

The small intestine's intrinsic design serves to provide a maximum amount of surface area for absorption of nutrients, water, and electrolytes. Specialized areas provide neurohormonal stimulation to the digestive tract. Its structure and vast surface area also provide an important physical barrier to potential pathogens, and certain areas are critical in immune surveillance.

GROSS ANATOMY AND EMBRYOLOGY

The small intestine spans from the pylorus to the ileocecal valve and includes three distinct regions: the duodenum, the jejunum, and the ileum. These areas combined measure, on average, approximately 5 meters and comprise nearly 62% of the entire length of the alimentary tract. The gastrointestinal tract is formed from the endodermal layer of the developing embryo. The small intestine is derived from the distal foregut (proximal duodenum), the midgut, and the adjacent splanchnic mesenchyme. Epithelium and glands develop from the embryonic endoderm, while connective tissue, muscle, and serosa develop from the mesoderm. During the fifth and sixth weeks of development, the duodenal lumen is temporarily obliterated due to proliferation of its mucosal lining. During the subsequent weeks, luminal vacuolization and degeneration of some of the proliferating cells result in recanalization of the duodenal lumen. From the 4th to the 10th week of development, a large portion of the midgut is herniated through the umbilicus. This may be due to the rapid growth of the intestinal tract at this time in relation to the abdominal cavity. At approximately 8 weeks of gestation, the midgut begins to

rotate in a counterclockwise manner 90 degrees around the axis of the mesenteric vasculature. The extra-abdominal portion of the gut returns to the abdominal cavity approximately 2 weeks later. Around this time point an additional 180-degree rotation occurs. These two rotations provide 270 degrees of total rotation and result in the typical anatomy that is found in humans. A failure of these precise steps produces a spectrum of anatomic variants that are grouped together as malrotation of the intestinal tract.¹

Duodenum

The duodenum makes up the first portion of the small intestine and plays an important role in connecting the foregut organs to the midgut. It anatomically begins at the duodenal bulb, which is immediately adjacent to the pylorus and terminates at the ligament of Treitz, where it joins the jejunum. The duodenum is approximately 20 to 30 cm in length and is divided into four distinct areas.

The first portion of the duodenum is approximately 5 cm in length and is referred to as the bulb or cap. This area is directly attached to the pylorus and extends laterally and cephalad. It serves as an attachment for the hepatoduodenal ligament and traverses over the common bile duct, portal vein, pancreatic head, and gastroduodenal artery. The mucosal surface of the duodenal bulb is smooth until its junction with the second portion of the duodenum, where the concentric Kerckring folds begin. This portion of the duodenum is prone to ulceration, with approximately 90% of duodenal ulcers occurring here. Unfortunately, due to its anatomic positioning, these ulcers may erode into the gastroduodenal artery, which lies

FIGURE 47.1. Arterial blood supply to the duodenum.

directly posterior to the duodenum, causing potentially life-threatening bleeding.

The second portion of the duodenum (descending duodenum) extends from the origin of the Kerckring folds to the beginning of the transverse duodenum and travels over the right renal vasculature, over the medial aspect of Gerota fascia, over the inferior vena cava, and to the right of the L1 and L2 vertebra. It is approximately 10 cm in length and 3 to 5 cm in diameter. The Kerckring folds (plicae circulares) are concentric mucosal folds that are 1 to 2 mm thick and 2 to 4 mm high and are separated by 2 to 4 mm of smooth, flat mucosa. This portion of the duodenum serves as an entry point for pancreatic and biliary secretions into the gastrointestinal tract. This is typically through the major papilla (ampulla of Vater), which is a valvular structure that arises in the midportion of the descending duodenum, approximately 7 to 10 cm from the pylorus. Through this point the confluence of the common bile duct and the main pancreatic duct (duct of Wirsung) join the duodenum. The valvular function of the papilla is regulated through the muscular sphincter of Oddi. The minor pancreatic duct (duct of Santorini) enters through a minor papilla proximal to the ampulla of Vater in 50% to 60% of patients and endoscopically appears as a 1- to 3-mm polypoid structure.

The second portion of the duodenum is important surgically as it represents the entry of the duodenum into the retroperitoneum. Surgical evaluation of this part of the duodenum requires mobilization from its posterior and lateral attachments, described as a Kocher maneuver. This allows for further evaluation of the duodenum, pancreatic head, and bile duct.

The third (transverse) and fourth (ascending) portion of the duodenum complete the duodenal sweep. The third portion of the duodenum is about 10 cm in length and courses transversely from right to left, crossing the midline anterior to the spine, aorta, and inferior vena cava. This portion is closely attached to the uncinate process of the pancreas. The superior mesenteric artery (SMA) and vein (SMV) course anterior to the third portion of the duodenum to provide blood supply to the gut. The transition between the third and fourth portion of the duodenum is marked by the passage of the SMA in front of the duodenum. The SMA forms an acute angle as it originates from the aorta. An abnormally narrow angle can result in obstruction of the duodenum at this location (SMA syndrome). The fourth portion of the duodenum is approximately 5 cm long and courses upward and obliquely to reach the ligament

of Treitz, marking the end of the duodenum and the return of the small bowel to the peritoneal cavity.

Following its embryologic origins, the vascular supply to the duodenum arises from branches of the celiac trunk for the foregut portion, whereas the distal (midgut origin) duodenum is supplied by branches of the SMA (Fig. 47.1). Venous drainage includes a series of pancreaticoduodenal veins that drain into the SMV–portal vein system. Lymphatic drainage follows the vascular supply with drainage to the pancreaticoduodenal nodes. From here, lymph drains superiorly to the hepatic nodes or inferiorly to the superior mesenteric nodes.

Jejunum and Ileum

- 2 Distal to the ligament of Treitz, the jejunum and ileum form the remainder of the small intestine. The boundary between the two is arbitrarily determined such that 40% of the intraperitoneal small intestine is composed of jejunum and 60% is composed of ileum. This portion of the bowel is suspended within the peritoneal cavity by a thin, broad-based mesentery that is attached to the posterior abdominal wall. The jejunum and ileum are freely mobile within the peritoneal cavity. The jejunum is the widest portion of the small intestine, whose caliber progressively decreases as it approaches the ileocecal valve. The mucosa of the jejunum has a thick lining and is characterized by prominent plicae circulares that become shorter and less frequent in the ileum. The total length of jejunum and ileum varies, but is usually 3 to 7 meters, with an average length of 5 meters. The small intestine terminates in the right lower quadrant at the ileocecal valve. The ileocecal valve exhibits motor characteristics separate from the terminal ileum and colon, postulated to prevent reflux of fecal material from the colon into the small intestine.²

The arterial blood supply of the jejunum and the ileum arises from the superior mesenteric artery. The main vascular branches form arcades within the mesentery. The vasa recta, intestinal arterial branches, enter into the intestinal wall without anastomosing. The vasa recta of the jejunum are straight and long, in contrast to the vasa recta of the ileum, which are shorter with greater arborization (Fig. 47.2). The venous and lymphatic drainage follow the arterial supply. The main venous outflow is through the superior mesenteric vein, which, along with the splenic vein, becomes the portal vein.

FIGURE 47.2. The superior mesenteric artery supplies blood flow into the small intestinal arteries (vasa recta), which branch within the mesentery. In the jejunum (A), the vasa recta are straight and long, in contrast to the vasa recta within the ileum (B), which are shorter with greater arborization.

MICROSCOPIC ANATOMY

General Considerations

The wall of the small intestine is composed of four distinct layers: mucosa, submucosa, muscle, and serosa. The role of the mucosa is absorption and secretion. The luminal mucosal surface forms circular folds known as plica circularis or valvulae conniventes in all segments of the small intestine distal to the first portion of the duodenum. The submucosa contains an elaborate network of blood vessels, lymphatics, and nerves. The muscular portion of the wall includes outer longitudinal and inner circular muscle layers. Between the muscle layers lies the myenteric (Auerbach) plexus. The muscular layers are responsible for coordinating peristaltic movements. The outermost layer, the serosa, is composed of a thin layer of mesothelial cells overlying loose connective tissue. The serosa covers only the anterior surface of the retroperitoneal segments of small bowel, but it completely covers the portions of small bowel that are invested with mesentery.

Mucosa

The mucosa lines the luminal surface of the small intestine. It consists of three layers: epithelial cells, lamina propria, and a narrow layer of smooth muscle, the muscularis mucosae. The basic structural units of the mucosa are crypts and villi. Villi are fingerlike projections of mucosa 0.5 to 1 mm high extending into the intestinal lumen that have a columnar epithelial surface and a cellular connective tissue core of lamina propria. Each villus contains a central lacteal (lymphatic) and a vascular network consisting of a small artery, vein, and capillaries. Ninety percent of the cells of the villi are columnar epithelial cells responsible for absorption and secretion. These cells are 22 to 25 μm high with basally located nuclei. The apices of these cells have microvilli, produced by numerous folds in the apical membrane, which account for the brush border appearance. Microvilli are approximately 1 μm long and 0.08 μm wide. Their surface is coated by glycoproteins rooted in the cell membrane. These glycoprotein filaments are referred to as the glycocalyx and are essential for digestion and absorption.³ The lateral membranes of neighboring enterocytes are connected by tight junctions, an apparent fusion of adjoining plasma membranes just below the level of the brush border. Movement of ions and water can occur by either a transmembrane or a paracellular route through tight junctions, which behave as selective pores.

Between the villi lie the crypts of Lieberkühn. Stem cells within the crypts of Lieberkühn are the source of the four major types of differentiated cells: the absorptive enterocyte, goblet cells, enteroendocrine cells, and Paneth cells. Absorptive enterocytes differentiate as they migrate from the crypt compartment up toward the tip of the intestinal villus. Cells then undergo apoptosis and are shed into the intestinal lumen. Most of the intestinal lining is renewed over a period of approximately 5 days. Despite the rapid rate of cellular turnover, intestinal epithelial cells exhibit complex patterns of gene expression that vary according to their location on the two main spatial axes of the gut, the vertical (crypt–villus) and horizontal (proximal to distal) axes. For example, cells destined to become enterocytes do not begin to express a variety of genes important in digestion and absorption until the cells have migrated out of the crypt and up the villus. In addition, many epithelial cell genes are selectively expressed in the proximal small intestine, whereas other genes are specifically expressed only in the ileum.⁴

Several other cell types are present in the mucosa. Mucus-secreting goblet cells are present in both the crypts and villi. Goblet cells have a narrow base containing the nucleus and a wide apical membrane with a large number of granules containing mucin. Mucin is secreted in a combination of merocrine and apocrine fashion by the goblet cell, functions as a lubricant, and has a cytoprotective function.⁵

Paneth cells are pyramidal cells that reside in the crypt base. They contain large eosinophilic secretory granules located at their apical surface. It is thought that Paneth cells play a role in host defense based on their abundant expression of lysozymes and defensins, a family of small peptides that are also found in human neutrophils and exhibit microbicidal activity toward many different bacterial organisms in vitro. However, examination of the role of Paneth cells in the small intestine by lineage ablation in transgenic mice revealed no alteration in host defense mechanisms; thus, the actual function of Paneth cells has yet to be delineated.⁶

Enteroendocrine (also referred to as *amine precursor uptake and decarboxylation*, or APUD) cells may reside in either the crypts or the villi, depending on the particular neuroendocrine substance they produce. Specific areas of the small intestine have higher concentrations of specific neuroendocrine substances than other areas. These cells do not contact the intestinal lumen, unlike exocrine cells, and their secretory

granules are located below the nucleus near the basement membrane. This suggests that these cells secrete their contents into the circulation rather than into the intestinal lumen.

Submucosa

- 4 The submucosa is a dense connective tissue layer with a rich network of blood vessels, nerves, and lymphatics. The submucosa contains the Meissner plexus and is the strongest layer of the intestinal wall. Brunner glands are found in the submucosa of the duodenum and secrete mucus and bicarbonate into the intestinal lumen. These secretions aid in the neutralization of the gastric acid load that enters the duodenum. Peyer patches are localized collections of lymphoid follicles that are most prominent in the submucosa of the ileum. These are typically 8 to 10 mm in diameter and are most abundant early in life, gradually disappearing with age.

PHYSIOLOGY

- 5 The small intestine plays important physiologic roles in motility, blood flow, growth, digestion, absorption, immune function, and endocrine secretion. In fact, the small intestine is the largest endocrine organ in the human body.⁷ The secretion of these numerous hormones and neurotransmitters is specific to distinct anatomic zones within the small intestine (Fig. 47.3). There is no specific cell mass that produces these hormones,

but rather individual cells scattered along the gastrointestinal tract.

Gastrin is a peptide produced in the gastric antrum and in the duodenum by the G cells and secreted into the circulation in response to gastric distention, vagal stimulation, amino acids, and hypercalcemia. Gastrin exists in three functional forms (G-34, G-17, G-14). Its release is inhibited by low intraluminal pH, somatostatin, secretin, gastric inhibitory peptide (GIP), vasoactive intestinal polypeptide (VIP), glucagon, and calcitonin. Gastrin binds to cholecystokinin 2 (CCK2)/gastrin receptors on enterochromaffin-like (ECL) cells, causing a release of histamine, which in turn stimulates the parietal cells in a paracrine fashion. Gastrin also causes an increase in the gastric blood flow and the release of pepsinogen by the chief cells and pancreatic enzymes from the pancreatic centroacinar cells.

CCK is produced in the proximal two thirds of the small intestine by the I cells and released into the gut lumen. It has four main forms (CCK-58, CCK-39, CCK-33, and CCK-8). It shares the final five amino acids adjacent to the C-terminus with gastrin, and this accounts for its hormonal activity. Stimulation of I cells by amino or fatty acids causes release of CCK, which in turn stimulates contraction and emptying of the gallbladder, increases bile flow, causes relaxation of the sphincter of Oddi, and stimulates pancreatic enzyme secretion. CCK also has trophic effects on the small-intestinal mucosa and pancreas.

Secretin, discovered as the first gastrointestinal hormone in 1902, is a 27-amino-acid peptide produced by the S cells of the

FIGURE 47.3. Distribution of peptide hormones in the gastrointestinal tract.

duodenum and jejunum. Secretin is released into the circulation and intestinal lumen in response to low intraluminal pH, fatty acids, and bile salts. Water and bicarbonate are secreted by the pancreas in response to secretin. Bicarbonate is also released from the biliary ductal epithelium and Brunner's glands in response to secretin. In turn, pancreatic enzymes are released from the pancreas. The increased pH and the presence of pancreatic enzymes aids in the digestion of lipids. The increased pH also provides a negative feedback loop to inhibit further production of secretin. Secretin produces a paradoxical release of gastrin in patients with gastrinomas, but does not produce this effect on normal individuals.

Somatostatin is a peptide hormone consisting of 14 or 28 amino acids and is produced by D cells in the pancreatic islets, gastric antrum, and duodenum. Its primary role is inhibition of other gastrointestinal hormones and inhibition of pancreatic, biliary, and gastric secretion. In addition, somatostatin decreases splanchnic and portal blood flow. Somatostatin is stimulated by the presence of fat, proteins, acid, glucose, amino acids, and cholecystokinin. Octreotide, a long-acting synthetic somatostatin analogue, is used in the treatment of variceal bleeding, hormone-secreting neuroendocrine tumors, carcinoid syndrome, and enterocutaneous and pancreatic fistulas.⁸

Gastrin-releasing peptide, the mammalian homologue of bombesin, is a 27-amino-acid peptide that is produced by the small intestine and is released in response to vagal stimulation. It is a prostimulatory molecule that causes the release of most gastrointestinal hormones, with the exception of secretin. It also has a promotility effect and stimulates endothelial proliferation. GIP or glucose-dependent insulinotropic peptide is a 42-amino-acid peptide produced by the K cells of the duodenum and jejunum. It is released in response to glucose, fat, protein, and adrenergic stimulation. It stimulates secretion of insulin and inhibits gastric acid and pepsin production. Type 2 diabetics are resistant to the effects of GIP.

Motilin is a 22-amino-acid peptide produced by the enteroendocrine cells in the duodenum and jejunum. Release of motilin occurs during the interdigestive and fasting periods. Release may also be related to alkalization of the duodenum. Motilin's main function is to stimulate the migrating myoelectric complex. Motilin agonists such as erythromycin are used clinically as stimulants of gastrointestinal motility.

VIP is a 28-amino-acid peptide that is produced by gastrointestinal tract neurons. It serves as a neurotransmitter stimulating pancreatic exocrine and intestinal secretion. Conversely, it has an inhibitory effect on gastric acid secretion. VIP is a potent vasodilator and relaxant of smooth muscle.

Neurotensin is a 13-amino-acid peptide that is produced by the N cells primarily in the ileum, but also in the proximal small intestine and colon in response to the presence of intraluminal fat. It stimulates pancreatic bicarbonate secretion and intestinal motility. Neurotensin also serves as a trophic factor on the small-intestinal mucosa and inhibits gastric secretion.

Pancreatic glucagon and enteroglucagon are 29- and 37-amino-acid peptides produced by the α -islet cells of the pancreas and the L cells of the small intestine, respectively. Pancreatic glucagon is released in response to low serum glucose and subsequently induces glycogenolysis, lipolysis, gluconeogenesis, and ketogenesis. Enteroglucagon is released in response to the presence of a mixed meal and inhibits gastric emptying and small-bowel motility.

Motility

- 6 The coordination of movements of the gastrointestinal tract is necessary for the proper digestion of food. Well-timed contraction and relaxation patterns are initiated in the gastrointestinal nervous system causing coordinated electrical activity and muscular movements. This may be influenced by both

FIGURE 47.4. Innervation of the gastrointestinal tract. The neural plexuses in the gut represent an independently functioning network, the enteric nervous system, which is connected to the central autonomic neural network in the central nervous system by parasympathetic and sympathetic nerves. The enteric nervous system may influence the effector system in the gut directly, or indirectly through its actions on intermediate cells, which include endocrine cells and cells of the immune system. The cell bodies of the primary vagal and primary splanchnic afferent neurons are located in the nodose ganglia and dorsal root ganglia, respectively; each carries distinct information from the gut to the central nervous system. The *pitchfork* symbols represent afferent nerve endings, and the *arrows* show the direction of neural transmission. (Adapted from Goyal RK, Hirano I. Mechanisms of disease: the enteric nervous system. *N Engl J Med* 1996;334:1106–1115.)

internal and external factors. The small intestine has motor functions that are distinct from the other parts of the gastrointestinal tract. The intrinsic nerves (myenteric or Auerbach plexus) provide the basis for coordinating the circular and longitudinal smooth muscles of the small intestine. Extrinsic sympathetic (epinephrine) stimulation slows motility, while parasympathetic (acetylcholine) stimulation increases motility (Fig. 47.4).

The intrinsic electrical activity of the small intestine is based on the intestinal smooth muscle normal resting potential. This normally is -50 to -70 mV and is maintained by $\text{Na}^+\text{-K}^+\text{-ATPase}$ activity.⁹ The resting potential varies by 5 to 15 mV and results in a phasic depolarization, which is referred to as slow waves, basic electrical rhythm, or pacemaker potential. These depolarizations occur at regular intervals of approximately 11 to 13 times per minute in the duodenum and decrease to 8 to 10 times in the ileum, but do not directly lead to muscular contractions. The electrical activity is coupled to muscular contraction at the level of gap junctions, which are low-resistance cell-to-cell connections. These gap junctions become less regular in the midjejunum and in the distal small intestine. This causes slowing of the frequency of contractions distally, allowing for absorption of more slowly digested intestinal contents, including fats and bile salts.

FIGURE 47.5. A: Recording of transmembrane potential showing slow waves and superimposed spike potentials. B: Extracellular recording of electrical activity represented in (A). C: Muscular contraction in response to electrical activity in (A). (Adapted from Christensen J. The control of gastrointestinal movements: some old and new views. *N Engl J Med* 1971;285:85–98.)

Spike potentials present a second mode of electrical stimulation of the small intestine, and result in rapid depolarization of the membrane potential. Repeated bursts of spike potentials cause a short area of contraction. In contrast to the always present slow waves, spike potentials occur at discrete time intervals. The coordination of a slow wave and a spike potential leads to the initiation, duration, and frequency of rhythmic migratory small-intestinal contractions (Fig. 47.5).

During the interdigestive period between feeding, the small intestine follows a well-defined rhythmic pattern. This pattern consists of muscular contractions that migrate from the stomach or duodenum, continue on to the terminal ileum, and are regulated by the migrating motor complex (MMC). This pattern can be broken down into four distinct phases. Phase I is a period of relative quiescence, phase II is a period of accelerated irregular electrical spiking and muscular activity, phase III is a series of high-amplitude rapid electrical spikes corresponding to rhythmic gut contractions, and phase IV is a period of subsiding activity. This process occurs over a period of 90 to 120 minutes and progresses from the proximal small bowel and terminates in the ileum. Once the MMC reaches the terminal ileum, the process starts over again in the proximal small bowel. The circular muscles provide segmental contraction over a 1-cm length of small intestine. These contractions occur approximately 11 to 13 times per minute in the duodenum and decrease to 8 to 10 times in the ileum. This creates functional compartments where prolonged exposure to the mucosa and mixing of the intestinal chyme occur, aiding the process of digestion and absorption. The circular muscles are also responsible for the peristaltic waves, which propagate regularly at a rate of 1 to 2 cm per second. These regular waves may be interspersed with rushes of contractions followed by periods of no motor activity. This rate becomes progressively slower in the distal small intestine. These peristaltic movements serve as a method of propelling chyme through the length of the small intestine. The total transit time from the duodenum to the terminal ileum is approximately 220 minutes (\pm 53 minutes).¹⁰ Serum motilin levels have been found to mirror the activity of the MMC. Exogenous motilin administration has been found to increase MMC activity.

During and immediately following times of feeding, the intestinal movements are not rhythmic, with complexes of peristaltic and antiperistaltic contractions. This is thought to be a disruption of the MMC from bolus feeding. This seemingly random pattern of movements allows for effective mixing of chyme. Hormonal changes are thought to play a role in

this process. Physiologic doses of neurotensin, insulin, gastrin, and CCK cause an alteration in the MMC similar to bolus feeding. Visual and olfactory feeding cues can also cause a disruption of the MMC. The MMC is more significantly inhibited by fatty meals as opposed to protein or carbohydrate meals of similar caloric value. The intrinsic nervous plexus or Meissner plexus innervating the submucosa helps to regulate mucosal absorption and secretion, but has no control on motility.

Immunology

7 Principles of Gut Immunology. The lumen of the gastrointestinal tract is connected to the outside environment and comes in direct contact with many potentially pathogenic microorganisms. Lymphocytes, macrophages, polymorphic granulocytes, and other cells that take part in the immune response are distributed throughout the whole gut. The commensal microflora have many benefits to the host by supporting digestion and keeping the appropriate balance among different microbial species.¹¹ The immune system is highly effective at responding selectively to invading pathogens yet on the other hand tolerating a much larger number of harmless food antigens and commensal organisms. Many bacteria, viruses, and parasites are digested and enter the small intestine every day.¹² Consequently, the small intestine needs a complex defense mechanism to battle against these exposures in different ways.¹³

While the immune system in the small intestine is important for host defense, other mechanisms within the small intestine also participate in host defense. Proteolytic and lipolytic enzymes are produced in high concentrations by extraintestinal cells in the pancreas and degrade different pathogenic agents at an early phase of digestion. In addition, mucin is produced by the enterocytes, which protects them and inhibits bacterial growth. Actively increased peristalsis functions to mechanically get rid of pathogenic agents and potentially dangerous gut content. In addition, tight junctions between epithelial cells prevent penetration of bacteria in between cells. Potential pathogens vary greatly in size, from very small viruses that are nanometers in size to parasites such as helminths that are macroscopically visible and quite large. To put this into the broader picture of evolution, a large range of defense mechanisms is essential for survival of each individual.

The primary cellular barrier in the gut that prevents antigens from encountering the immune system is the single layer of gut epithelium. The total surface area of the small intestine is 400 m², due not only to intestinal length but also to the formation of millions of villi in the small bowel, which contribute significantly to the overall surface area.¹⁴ In the upper small intestine, the bulk of antigen exposure comes from the diet, whereas in the ileum and colon, the additional antigenic load of an abundant and highly complex commensal microflora is prevalent. The epithelial cells of the gut mucosa have developed features that make the intestinal epithelium an active immunologic as well as anatomic barrier. For example, these nonclassical immune cells express major histocompatibility complex (MHC) class I and II molecules, consistent with their ability to participate in adaptive immune recognition of pathogenic bacteria. Small-intestinal epithelial cells also express Toll-like receptors on their apical surface that enables them to detect bacterial products and to initiate an innate immune response. Antigen-presenting dendritic cells (DCs) also send processes between gut epithelial cells without disturbing tight junction integrity and sample commensal and pathogenic gut bacteria.^{15,16} The gut epithelial barrier therefore represents a highly flexible structure that limits antigens from entering the systemic circulation.

The gut-associated immune system represents one of the largest immunologic compartments in the body. Lymphoid

tissue in the gastrointestinal tract is a major part of the whole body immune system and consists of both aggregated (lymphoid follicles, Peyer patches) and nonaggregated (luminal, intraepithelial, and in lamina propria) immune cells. Under physiologic circumstances, oral administration of protein antigens induces systemic unresponsiveness when the same antigen is given parenterally (a phenomenon known as oral tolerance). In animal models, oral tolerance appears to be a specific consequence of the immune environment in the gut, which favors the generation of regulatory T cells.

Nonaggregated and Aggregated Lymphoid Tissue.

The gut epithelium and its mucous layer form a major barrier to trap pathogens, which are then eliminated when the gut epithelium is shed and replaced by new cells deriving from stem cells in the crypts. Several different cell types face antigenic exposure present in the intestinal lumen and include the epithelium, neutrophils, lymphocytes, and macrophages. These luminal cells represent an initial effector mechanism in the first front directed toward an antigenic exposure. In addition, there are also intraepithelial lymphocytes, which migrate and are found between epithelial cells beneath the tight junctions. Local defense depends in part on these T lymphocytes that are nestled among gut epithelial cells. These T cells modulate homeostasis of the gut epithelium through local production of cytokines and have cytolytic effects. In fact, the number of intraepithelial lymphocytes can increase dramatically in response to inflammation or infection. After exposure to antigens, these cells reenter the circulation to initiate a systemic immune response. The lamina propria contains nonaggregated, diffusely distributed lymphoid tissue, including different types of immune cells (Fig. 47.6). B cells in the lamina propria undergo cytokine-induced differentiation in the lamina propria to become active producers of immunoglobulin A (IgA), which is secreted into the gut lumen. T cells in the

lamina propria may have a different role in a helper-inducer function for immunoglobulin production rather than a cytolytic function. Mast cells and eosinophils are also present in the lamina propria in small numbers. They exhibit an important role in allergic and hypersensitivity reactions as well as defense against parasites. Parasites including worms are recognized and tagged using monovalent IgE, which is mostly bound to host cell surfaces. Actual parasite killing depends on toxic proteins secreted by eosinophils.

There are also large aggregates of lymphoid tissue found in the small intestine. These so-called Peyer patches are localized collections of lymphoid follicles that are most prominent and macroscopically visible in the submucosa of the ileum. Peyer patches are most prominent in children and gradually disappear with age. Along with the nonaggregated immune system, the enormous quantity and diversity of antigens present within the gut are also processed via Peyer patches in the lamina propria and the mucosa-associated lymphoid tissue (MALT), which in total contains about 70% of the body's lymphoid cells. Another often used term to describe the immune system within the small intestine is gut-associated lymphoid tissue (GALT). Peyer patches do not have any villi, and so-called microfold (M) cells concentrated within the epithelium allow the selective uptake of food antigens and microorganisms (Fig. 47.7). M cells are specific cells in the intestinal epithelium over lymphoid follicles that endocytose antigens. M cells transport them into the underlying tissue, where they are taken up by local dendritic cells and macrophages.¹⁷ Dendritic cells and macrophages that receive antigens from M cells present them to T cells in the gut-associated lymphoid tissue, leading ultimately to the appearance of IgA-secreting plasma cells in the mucosa. B-lymphocyte precursors proliferate in germinal centers within the Peyer patches. Dendritic cells below the epithelium can also take up luminal antigens by pushing pseudopods up between epithelial cells.

FIGURE 47.6. Small-intestinal villus with associated immunologic cells.

FIGURE 47.7. Epithelial anatomy in the area of Peyer patches.

Immunoglobulin Secretion. At an early level of exposure at the gut epithelium, M cells take up antigen and transport it transcellularly using an endocytic mechanism into the underlying lymphoid tissues of Peyer patches. Lymphocyte activation ensues, and these activated lymphocytes migrate into afferent lymphatics, pass through mesenteric lymph nodes, and enter the systemic circulation through the thoracic duct. During this process, the lymphocytes mature into B and T lymphoblasts with an enriched population of IgA-producing B cells.¹⁸ Passage of viable bacteria from the intact gastrointestinal tract to the mesenteric lymph node and beyond has been termed *bacterial translocation*, possibly explaining septic complications and multiple organ failure in peritonitis, burn, and trauma patients. The immunogenic integrity of the mucosa is significantly damaged by systemic injury of different kinds. A major protective mechanism of the intestinal immune system is synthesis and secretion of IgA. In the intestine, IgA exists as a dimer that is linked with two additional molecules—the J chain—linking two IgA molecules and the polymeric immunoglobulin receptor, which transports the IgA complex across the cell and allows release of the complex, termed *secretory component*, into the intestinal lumen. The transmembrane immunoglobulin receptor is produced by the intestinal epithelial cell. It is thought that the secretory component may prevent proteolytic degradation of the IgA molecule and may stabilize the structure of the polymeric IgA complex in an environment containing numerous proteolytic enzymes and bacteria that would otherwise rapidly degrade it. Unlike IgG and IgM, IgA does not activate complement and does not promote cell-mediated opsonization. The major function of secretory IgA in host defense is protection against bacteria, viruses, and luminal antigens. Secretory IgA inhibits the adherence of bacteria to epithelial cells. It is well known that a breast-feeding mother transfers secretory IgA to her nursing infant, protecting the infant from bacteria and viruses that were originally present in the mother's gastrointestinal tract.

Digestion and Absorption

Absorption of Water and Electrolytes. An average person consumes approximately 1 to 1.5 L of water per day. An additional 5 to 10 L is secreted by the gastrointestinal tract: 1 to 2 L of saliva, 2 to 3 L of gastric secretions, 0.5 L of biliary secretions, 1 to 2 L of pancreatic juice, and 1 L of intestinal secretions. The small intestine reabsorbs nearly 80% of the fluid that passes through it. This dynamic process is accomplished by a rapid bidirectional movement of fluid in the

intestinal lumen. This ebb and flow of fluid in the intestinal lumen is critical in maintaining normal homeostasis. Minor changes in intestinal permeability or rate of flow of the intestinal contents can result in net secretion and diarrheal states.

The tonicity of the intraluminal contents determines the overall net movement of water. In general, after a meal is consumed, the addition of large amounts of saliva, gastric juice, and hypotonic chyme enters the proximal small intestine. Acid gastric contents are neutralized by the secretion of bicarbonate, creating NaCl and water and decreasing the osmotic pressure. The jejunum is effective at passively reabsorbing water in a paracellular fashion due to its relatively large intercellular pores. As the chyme travels through the length of the small intestine, the intercellular channels become more tightly arranged and the movement of water becomes dependent on the active transport of solutes into the paracellular spaces. A total of 6 to 11 L of water enters the duodenum every day; of this, approximately 1 to 1.5 L enters the colon.

Sodium absorption occurs through several different processes. Simple electrogenic absorption, non-electrolyte-stimulated absorption, and electroneutral absorption are reliant on the Na^+ - K^+ -ATPase pump on the basolateral membrane of the cell. This pump utilizes the hydrolysis of ATP to provide the necessary energy to move three Na^+ ions out of the cell while transporting two K^+ ions into the cell against an electrical gradient. This process maintains a negatively charged low Na^+ intracellular environment, allowing for several mechanisms of absorption at the apical membrane. Simple electrogenic absorption of sodium is the process of an influx of Na^+ ions from the sodium-rich intestinal lumen into the negatively charged low-sodium intracellular environment. This process is indirectly energy dependent, as it relies on the function of the Na^+ - K^+ -ATPase pump on the basolateral membrane to maintain the low-sodium environment and the negative intracellular charge. This process can be inhibited by ouabain, a Na^+ - K^+ -ATPase inhibitor.¹⁹

Non-electrolyte-stimulated sodium absorption occurs when sodium is coupled with an organic solute, such as glucose, amino acids, dipeptides, tripeptides, and bile acids. Sodium is preferentially transported down its electrochemical gradient, which is created by the Na^+ - K^+ -ATPase pump on the basolateral membrane of the cell, providing the necessary energy to transport the organic solute against its gradient (Fig. 47.8A). Electroneutral absorption of sodium chloride occurs through a process that couples two neutral ion countertransport mechanisms. Na^+ is exchanged for H^+ and Cl^- is exchanged for HCO_3^- , resulting in no net change in intracellular charge. This

FIGURE 47.8. Mechanisms of sodium absorption in the small intestine: solute-coupled Na^+ absorption (A) and electroneutral NaCl absorption (B).

process provides an influx of NaCl in exchange for H^+ / HCO_3^- efflux. This electroneutral transfer of ions allows for intracellular pH regulation and for sodium and chloride transport (Fig. 47.8B).

While the majority of chloride is absorbed by electroneutral transfer, chloride is also absorbed by passive diffusion in a paracellular fashion. This is due to the slightly positive interstitium when compared to the gut lumen, allowing the negatively charged chloride ions to be absorbed. An additional important source of chloride transport involves the reabsorption of chloride ions contained within gastric hydrochloric acid secretions. Chloride is a major determinant of the regulation of fluid secretion into the small intestine and in intestinal hydration.²⁰

Bicarbonate absorption occurs primarily in the jejunum and requires the formation of carbon dioxide in the intestinal lumen from HCO_3^- and H^+ . This creates an increase in the partial pressure of carbon dioxide in the intestinal lumen. Carbon dioxide subsequently diffuses back into the enterocyte and is enzymatically cleaved into H^+ and HCO_3^- by the action of carbonic anhydrase. HCO_3^- diffuses into the interstitium and H^+ is resecreted in exchange for other cations, predominantly Na^+ . In the duodenum and ileum, HCO_3^- is secreted in exchange for Cl^- . This efflux of HCO_3^- provides a mechanism to neutralize gastric acid entering into the duodenum. HCO_3^- secretion in the ileum most likely helps maintain acid-base equilibrium, although this process is not well understood.²¹

Approximately 90 mEq/d of potassium is ingested in a normal diet, of which 90% is absorbed. An equal amount of potassium is excreted in the urine as is absorbed in the intestine, allowing maintenance of potassium homeostasis. The majority of absorption occurs in the small intestine, mainly through passive mechanisms.²² This process is thought to occur through intercellular pores or through a H^+ - K^+ exchange pathway facilitated by the intracellular electrochemical gradient that is created predominantly by the basolateral ATPase pump. Intracellular K^+ then diffuses across the basolateral membrane by a K^+ channel or carrier.

Mineral Absorption. Mineral absorption is necessary for the proper form and function of the human body. These inorganic elements are responsible for approximately 4% to 6% of a person's mass. Calcium accounts for approximately 50% of this mass, phosphate provides an additional 25%, and a variety of other minerals constitute the remaining 25%. Many of these minerals are best absorbed in their ionized forms, which is aided

by the presence of hydrochloric acid in the gastric lumen. Calcium, phosphate, magnesium, sulfur, sodium, chloride, and potassium are considered macrominerals, with daily requirements exceeding 100 mg/d. Microminerals (trace minerals) include iron, zinc, copper, manganese, iodine, selenium, fluoride, molybdenum, chromium, and cobalt with daily requirements of less than 15 mg/d.

Approximately 1 g of calcium is consumed per day, mainly from dairy products. Once in its ionized form, calcium is primarily absorbed in the duodenum, although this process occurs throughout the length of the small intestine. When calcium is present intraluminally at low levels, it is transported across the apical membrane of the enterocyte by carrier-mediated facilitated diffusion. Once calcium is in the cytoplasm, it is bound to calcium-binding proteins and delivered to the basal membrane. Calcium is then transferred into the interstitium by a Ca^{2+} -ATPase pump. This process is indirectly regulated by parathyroid hormone (PTH). PTH in low-calcium states promotes conversion of vitamin D to its active form, 1,25(OH)₂ vitamin D. This activated form of vitamin D causes an increase in the expression of both calcium-binding proteins and Ca^{2+} -ATPase, causing an increase in the absorption of calcium by the small intestine.^{23,24} When intraluminal calcium is in excess of its capacity to be actively transferred by the apical membrane's carrier-mediated mechanism, passive paracellular calcium absorption occurs in the distal small intestine.

Absorbable dietary sources of iron are typically either contained within a protein, such as heme, or as a ferrous Fe^{2+} ion. Iron-containing proteins are usually from ingested meats, whereas ferrous forms are typically present in vegetables, grains, and fruits. Vitamin C (ascorbic acid) increases iron absorption by reducing the ferric (Fe^{3+}) ion into the more soluble ferrous state. Absorption of iron is facilitated by carrier-mediated translocation across the apical membrane of the enterocyte in the duodenum and proximal jejunum. Once in the cytoplasm, the ferrous ion is released by enzymatic cleavage. Ferrous ions may be stored intracellularly by ferritin or transported into the circulation by transferrin. The process of iron absorption is regulated in the enterocyte by hypoxia-inducible factor signaling and iron-regulatory proteins. Systemically, the central iron-regulatory hormone is hepcidin. Hepatic hepcidin regulates iron absorption and mobilization from systemic stores by inhibiting ferroportin, a cellular iron exporter.²⁵

Carbohydrate Digestion and Absorption. Carbohydrates are a staple in many diets and provide a major source of

FIGURE 47.9. Digestion and absorption of carbohydrates.

daily caloric intake. In Western diets 400 g of carbohydrates are consumed by the average adult daily, providing 1,600 kcal (4 kcal/g of carbohydrate). Carbohydrates are present in three main digestible forms: complex starches, disaccharides, and simple sugars. Complex starches account for approximately 60% of daily carbohydrate intake. The most common form is amylopectin, which consists of glucose linked in a linear fashion with $\alpha(1,4)$ -glycosidic bonds with branch points consisting of $\alpha(1,6)$ -glycosidic linkages occurring after approximately every 20 to 26 glucose moieties. Amylose is a long linear grouping of glucose molecules connected with $\alpha(1,4)$ -glycosidic bonds without branch points. Disaccharides, mainly sucrose and lactose, are the next most common source of dietary carbohydrates, representing nearly a third of daily intake. Sucrose disaccharides are composed of glucose-fructose dimers, whereas lactose disaccharides consist of glucose-galactose dimers.

The complex starches amylopectin and amylose are digested with the aid of salivary and pancreatic amylase. Salivary amylase contributes a small amount to this process as it is inactivated by gastric acid, leaving the remainder of this process to be completed by pancreatic amylase. This process yields maltose, which is a glucose dimer with $\alpha(1,4)$ -glycosidic bonds, and maltotriose, which is a glucose trimer with $\alpha(1,4)$ -glycosidic bonds. In addition, α -dextrins are produced with an average of six glucose moieties with $\alpha(1,4)$ -glycosidic bonds and side branches linked by $\alpha(1,6)$ -glycosidic bonds. This digestive process is usually completed before the carbohydrate bolus leaves the duodenum. These small oligosaccharides along with ingested disaccharides, typically sucrose and lactose, are then further digested by the brush border saccharidases in the jejunum.

The brush border of the small bowel contains specific enzymes that through catalytic reactions hydrolyze these oligo- and disaccharides into their component monosaccharide moieties, such as glucose, galactose, and fructose. Once broken down into their basic subunits, these monosaccharides can be

transported across the apical cell membrane. A sodium-dependent hexose transporter (SGLT-1) is required for the transport of glucose and galactose as they utilize the same carrier mechanism. The cotransportation of these monosaccharides with sodium is dependent on the Na^+ -K⁺-ATPase pump on the basolateral membrane to maintain a sodium gradient allowing for this influx. Fructose is transported in a carrier-mediated diffusion-dependent manner by GLUT5 and does not require sodium as a cotransporter (Fig. 47.9). The movement of monosaccharides into the cellular cytoplasm provides an additional gradient by which water is absorbed by the enterocytes from the intestinal lumen. The monosaccharides are then transported across the basolateral membrane by GLUT2. This hexose transporter allows for the diffusion of all three monosaccharides into the extracellular space and ultimately into the portal blood flow. A small portion of these monosaccharides may be used by the enterocyte, but the majority are transported through the cell.

Nondigestible carbohydrates (dietary fiber) such as cellulose are thought to be an important part of a normal diet even though they do not provide dietary calories. Dietary fiber is present in grains, vegetables, and pulpy fruits. Dietary fiber helps decrease bowel transit time by absorbing water in the intestinal lumen. In addition, fiber can absorb organic materials such as lipids and bile salts and inorganic minerals such as zinc, calcium, and magnesium. These actions of fiber are thought to play a role preventing carcinogenesis and in helping to maintain normal serum lipid profiles. Unfortunately, fiber is underrepresented in most Western diets.

Protein Digestion and Absorption. Protein consumption is essential to the daily diet. An average adult requires 0.75 g/kg of protein per day, although this requirement may be significantly increased during childhood, pregnancy, and times of significant illness. Protein provides an important caloric energy source as well as the essential building blocks for production of new proteins. A nearly equal amount of protein is

ingested daily from dietary sources (70 to 100 g) as is provided by endogenous proteins (50 to 60 g of protein per day) in the small intestine from secreted enzymes, desquamated cells, and plasma protein leakage. Nearly 90% of this protein load is metabolized in a similar fashion to dietary proteins.

The initial digestion of protein begins with the activation of pepsinogen to pepsin in the acid environment of the stomach. Pepsin hydrolyzes protein into its component amino acids; however, this action only represents a small part of overall protein digestion. The majority of protein digestion occurs in the small intestine by pancreatic peptidases and proteases. Pancreatic enzymes flow into the duodenum, initiating this phase of protein digestion. These pancreatic proteases are initially released as proenzymes (zymogens). These zymogens are inactive and require a further catalytic process to occur for their activation. This is initiated by the brush border enzyme enteropeptidase (enterokinase) in the duodenum. Endopeptidase cleaves trypsinogen into the active enzyme trypsin. Trypsin in turn activates the other zymogens into their active endopeptidases (trypsin, chymotrypsin, and elastase), which hydrolyze internal peptide bonds. Additional protein digestion is performed by exopeptidases (carboxypeptidase A and B), which are able to cleave amino acids from the C-terminal ends of proteins. Seventy percent of the process results in short oligopeptides of two to six amino acids and the remaining 30% produces single amino acids.

Short oligopeptides are further digested by enzymes in the brush border of the small intestine or within the cell cytoplasm. Single amino acids, dipeptides, and tripeptides are able to diffuse through the apical membrane into the cytoplasm. Single amino acids are cotransported into the cytoplasm with sodium along an electrochemical gradient. This electrochemical gradient is maintained by the $\text{Na}^+\text{-K}^+\text{-ATPase}$ pump on the basolateral cell membrane. At least four separate transport mechanisms exist for the various electrochemical properties of amino acids that are transported (neutral, dibasic, acidic, and imino). Peptides greater than three amino acids in length are broken down into smaller peptides by enzymes in the brush border. The resultant dipeptides and tripeptides are then moved into the cytoplasm along with H^+ by a cotransporter PepT1 , where they are hydrolyzed by specific peptidases into their component amino acids. Transport of amino acids into the cytosol provides an osmotic gradient by which water is further absorbed from the intestinal lumen. A small portion of the processed amino acids is utilized by the enterocyte, and the vast majority are shuttled into the portal blood flow via amino acid transporters on the basolateral membrane.

Fat Digestion and Absorption. Forty percent of the average daily caloric intake (60 to 90 g) in a Western diet is in the form of fat. Ninety percent of these ingested fats are triglycerides, while the remainder is composed of cholesterol, phospholipids, and fat-soluble vitamins. The initiation of lipid digestion occurs when CCK is stimulated by the presence of fatty acids on the duodenal mucosa. CCK in turn stimulates pancreatic secretion of lipase and its cofactor colipase. Lipase hydrolyzes triglycerides at the 1 and 3 position of the glycerol backbone, yielding two fatty acids and a monoglyceride (a fatty acid esterified to glycerol). Cholesterol and fat-soluble vitamins are hydrolyzed by pancreatic cholesterol esterase and phospholipids by phospholipase A_2 . The products of lipolysis interact with bile salts to form water-soluble micelles. Mixed micelles are 50 to 400 Å in diameter and are a combination of fatty acids, bile salts, and monoglycerides. The structure of a micelle is composed of an inward-facing hydrophobic region and a hydrophilic region facing outward toward the aqueous environment of the intestinal lumen. Due to the hydrophobic core, cholesterol, phospholipids, and fat-soluble vitamins can reside within the micelle structure. Micelles are able to interact with the mucosal cells and empty their contents into the cytoplasm. This occurs by the process of dissolution of the micelles

into the lipid bilayer of the mucosal cell. Once this is completed, the components of the micelle are ready to re-form with new lipid components to repeat this process. There is no energy consumed directly in the transfer of lipids into the cell cytoplasm.

Once in the cytoplasm, long-chain fatty acids and β -monoglycerides are carried by cytosolic fatty acid-binding proteins to the smooth endoplasmic reticulum (SER). In the SER, resynthesis of triglycerides occurs. These triglycerides are further processed in the Golgi apparatus where a phospholipid and an apoprotein coat are added to form a chylomicron. Chylomicrons are 90% triglyceride; the remaining 10% is composed of phospholipid, cholesterol, and protein. These large particles are 750 to 6,000 Å in diameter. Before exiting the Golgi apparatus, the chylomicrons are packaged into secretory vesicles. They exit the cell membrane by exocytosis and enter the central lacteal of the villus and the intestinal lymphatic system. In addition, enterocytes also produce smaller lipoprotein particles, very-low-density lipoproteins, which contain a higher cholesterol/triglyceride ratio and provide the major route of entry for dietary cholesterol into the lymphatic system.

Short-chain fatty acids contain less than eight carbon atoms and are water soluble. This allows these molecules to enter and exit the enterocyte by simple diffusion independent of bile micelles or chylomicrons. Medium-chain triglycerides consist of 6 to 12 carbon atoms and can be absorbed by simple diffusion or through the previously mentioned process of transport of long-chain fatty acids via the formation of bile micelles and chylomicrons. Both short- and medium-chain fatty acids may enter the portal circulation without entering into the lymphatics. The majority of dietary fat is processed and absorbed in the duodenum and upper jejunum.

Absorption of Bile Salts. Approximately 95% of the bile salts secreted into the intestine are reabsorbed and returned to the liver through the portal circulation. Once in the liver, these bile salts are reprocessed and secreted and stored in the gallbladder in preparation for the next meal. This process of recycling bile salts is referred to as the enterohepatic circulation. This reabsorption occurs by both passive and active means. A small amount of bile salts are passively reabsorbed along the entire length of the small intestine. The majority of bile salts, however, are reabsorbed through an active Na^+ -dependent transport mechanism in the terminal ileum. Bile, which is not reabsorbed, passes into the colon where it is deconjugated by bacteria. This process increases the solubility of the bile and promotes further passive absorption. High concentrations of bile salts within the colon inhibit sodium and water reabsorption, resulting in diarrhea. Patients who have undergone resection of their ileum may suffer from diarrhea due to this process. These patients may be treated with the bile-binding resin cholestyramine to help alleviate their symptoms.

Vitamin Absorption. Fat-soluble vitamins (A, D, E, and K) are incorporated into micelles along with fats in order to pass into the enterocyte. These vitamins are then processed and packaged into chylomicrons so that they can exit into the lymphatic system. Water-soluble vitamins are absorbed in the jejunum and ileum through a variety of mechanisms. Vitamin C (ascorbic acid), biotin, and niacin are transported by Na^+ -dependent mechanisms. Folate, vitamin B_1 (thiamine), and vitamin B_2 (riboflavin) are absorbed by Na^+ -independent mechanisms, and vitamin B_6 is absorbed by passive diffusion.²⁶

Vitamin B_{12} (cobalamin) absorption is dependent on the presence of intrinsic factor, a glycoprotein produced by the gastric parietal cells. One molecule of intrinsic factor binds two molecules of cobalamin to form a complex that attaches to a specific membrane receptor in the terminal ileum. Unbound cobalamin cannot be absorbed. Cobalamin becomes unbound from its complex in the enterocyte and exits from the cell into the portal circulation with the aid of B_{12} -binding proteins

called transcobalamins. Cobalamin is essential for DNA synthesis, and a deficiency usually presents with megaloblastic anemia. Inability to absorb sufficient amounts of cobalamin may be due to lack of intrinsic factor after proximal or total gastrectomy, autoimmunity to gastric parietal cells or intrinsic factor, or atrophic gastritis. In addition, cobalamin–intrinsic factor complexes may fail to be absorbed due to distal ileal disease or resection, and cobalamin deficiency may occur from bacterial overgrowth due to bacterial overconsumption of cobalamin.

CHAPTER 48 ■ ILEUS AND BOWEL OBSTRUCTION

DAVID I. SOYBEL AND WENDY B. LANDMAN

KEY POINTS

- 1 In simple obstruction the intestinal lumen is partially or completely occluded without compromise of intestinal blood flow. Simple obstructions may be complete, meaning that the lumen is totally occluded, or incomplete, meaning that the lumen is narrowed but permitting distal passage of some fluid and air. In strangulation obstruction, blood flow to the obstructed segment is compromised and tissue necrosis and gangrene are imminent.
- 2 The four key symptoms that are associated with acute mechanical bowel obstruction include abdominal pain, vomiting, distention, and obstipation.
- 3 Peritoneal adhesions account for more than half of small-bowel obstruction cases.
- 4 Ileus denotes underlying alterations in motility of the gastrointestinal tract, leading to functional obstruction.
- 5 Postoperative ileus can be differentiated from small-bowel obstruction with the use of contrast computed tomography and enteroclysis imaging techniques.
- 6 Postoperative ileus (POI) is often self-limiting; less frequent interventions are required for prolonged POI if proper precautions have been taken during surgery.

INTRODUCTION AND HISTORICAL PERSPECTIVE

The purpose of this chapter is to provide an overview of the pathophysiology, natural history, diagnosis, and management of acute obstruction and ileus of the small and large intestines. The development of the modern approach to intestinal obstruction and ileus paralleled the development of techniques for safe abdominal surgery. Chief among these accomplishments were the discovery of safe general anesthetics, the popularization of

aseptic methods in the operating room and in the management of wounds, and the development of techniques for intestinal resection, intestinal anastomosis, and colostomy. The foundations of the recognition and management of intestinal obstruction and ileus are attributed to Frederick Treves.^{1–3} In 1884, he published a detailed discussion of the etiologies (including adhesions) and surgical management of mechanical intestinal obstruction.¹ Treves also distinguished mechanical from non-mechanical (i.e., paralytic) causes of intestinal distention, classifying the latter causes under the term *ileus*. From 1880 to 1925, proximal intestinal decompression was recognized to

provide relief from the symptoms of mechanical obstruction or ileus.³ In 1933, Wangenstein and Paine reported the efficacy of gastrointestinal intubation in relieving symptoms of intestinal distention caused by intestinal obstruction or from the ileus that resulted from laparotomy.^{4,5} Subsequently, Wangenstein and Rea provided experimental evidence that the source of gaseous distention in cases of obstruction or ileus was swallowed air.⁶ The value of intravenous fluid resuscitation in experimental models of intestinal obstruction was recognized as early as 1912⁷ and became a principle of care of the patients with intestinal obstruction in the late 1920s. By 1920, plain abdominal radiographs were used in diagnosis of intestinal obstruction.³ Thus, the principles of early diagnosis, rapid intravenous fluid resuscitation, gastrointestinal decompression, and early operation to avoid intestinal gangrene and peritonitis were established well before the advent of antibiotic therapy, invasive hemodynamic monitoring, and parenteral nutrition.⁸ These early developments were most important in reducing morbidity and mortality of mechanical intestinal obstruction and ileus.⁹

MECHANICAL OBSTRUCTION OF THE INTESTINES

Terminology and Classification

The term *mechanical obstruction* means that luminal contents cannot pass through the gut tube because the lumen is blocked. This obstruction is in contrast with *neurogenic* or *functional* obstruction in which luminal contents are prevented from passing because of disturbances in gut motility that prevent coordinated peristalsis from one region of the gut to the next. This latter form of obstruction is commonly referred to as *ileus* in the small intestine and *pseudo-obstruction* in the large intestine. In *simple* obstruction the intestinal lumen is partially or completely occluded without compromise of intestinal blood flow. Simple obstructions may be *complete*, meaning that the lumen is totally occluded (Fig. 48.1), or *incomplete*, meaning that the lumen is narrowed but permitting distal passage of some fluid and air. In *strangulation*

FIGURE 48.1. Schematic illustration of different forms of simple mechanical obstruction. Simple obstruction is most often due to adhesion (A), groin hernia (B), or neoplasm (C). The hernia can act as a tourniquet, causing a closed-loop obstruction and strangulation.

TABLE 48.1

CLASSIFICATION OF ADULT MECHANICAL INTESTINAL OBSTRUCTIONS

■ INTRALUMINAL	■ INTRAMURAL	■ EXTRINSIC
Foreign bodies	Congenital (rare in adult)	Adhesions
Barium inspissation (colon)	Atresia, stricture, or stenosis	Congenital: Ladd or Meckel bands
Bezoar	Web	Postoperative
Inspissated feces	Intestinal duplication	Postinflammatory (after pelvic inflammatory disease)
	Meckel diverticulum	Hernias
	Inflammatory process	Abdominal wall
	Crohn disease	Internal
Gallstone ileus	Diverticulitis	Volvulus
	Stricture from ischemia	External mass effect
	Radiation enteritis or stricture	Abscess
Meconium (cystic fibrosis)	Medication induced (nonsteroidal anti-inflammatory drugs, KCl tablets)	Annular pancreas
		Pancreatic pseudocyst
Parasites (ascaris, diphyllbothrium)	Neoplasms	Carcinomatosis
	Primary intestinal or colon (malignant or benign)	Endometriosis
Enterolith	Secondary (metastasis or carcinomatosis)	Pregnancy
Intussusception		
Polypoid and exophytic lesions	Trauma (e.g., intramural hematoma)	

obstruction, blood flow to the obstructed segment is compromised and tissue necrosis and gangrene are imminent. Strangulation usually implies that the obstruction is complete, but some forms of partial obstruction can also be complicated by strangulation.

The various forms of mechanical intestinal obstruction can be classified according to different but overlapping schemes. Most commonly, obstruction is classified according to etiology. As detailed in Table 48.1, distinctions are drawn between intraluminal obturators such as foreign bodies or gallstones, intramural lesions such as tumors or intussusceptions, and extrinsic or extramural lesions such as adhesions. In order to

highlight the pathophysiology, presentation, and natural history, however, it is useful to classify obstruction according to the location of the obstructing lesion. Proximal or “high” obstructions involve the pylorus, duodenum, and proximal jejunum. Intermediate levels of obstruction involve the intestine from the midjejunum to the midileum. Distal levels of obstruction arise in the distal ileum, ileocecal valve, and proximal colon, whereas the most distant or “low” obstructions would arise in regions beyond the transverse colon. As shown in Table 48.2, clinical symptoms and signs of obstruction (pain, vomiting, abdominal distention, gas pattern on abdominal radiographs) vary with the level of obstruction.

TABLE 48.2

SYMPTOMS AND SIGNS OF BOWEL OBSTRUCTION

■ SYMPTOM/ SIGN	■ PROXIMAL SMALL BOWEL (OPEN LOOP)	■ DISTAL SMALL BOWEL (OPEN LOOP)	■ SMALL BOWEL (CLOSED LOOP)	■ COLON/RECTUM
Pain	Intermittent, intense, colicky, often relieved by vomiting	Intermittent to constant	Progressive, intermittent to constant, rapidly worsens	Continuous
Vomiting	Large volumes, bilious and frequent	Low volume and frequency, progressively feculent with time	May be prominent (reflex)	Intermittent, not prominent; when present, feculent
Tenderness	Epigastric or periumbilical; quite mild, unless strangulation is present	Diffuse, progressive	Diffuse, progressive	Diffuse
Distention	Absent	Moderate to marked	Often absent	Marked
Obstipation	May not be present	Present	May not be present	Present

Adapted from Schuffler MD, Sinanan MN. Intestinal obstruction and pseudo-obstruction. In: Sleisenger MH, Fordtran JS, eds. *Gastrointestinal Disease*, 5th ed. Philadelphia, PA: WB Saunders; 1993:898–916.

FIGURE 48.2. Schematic illustration of a closed-loop obstruction. The small intestine twists around its mesentery, compromising inflow and outflow of luminal contents from the loop. Also, the vascular supply to the loop may be compromised due to the twisting of the mesentery. The risk of strangulation is high.

It is also important to distinguish between *open-loop* and *closed-loop* obstructions. An open-loop obstruction occurs when intestinal flow is blocked but proximal decompression is possible through vomiting. A closed-loop obstruction occurs when inflow to the loop of bowel and outflow from the loop are both blocked. This obstruction permits gas and secretions to accumulate in the loop without a means of decompression, proximally or distally. Examples of closed-loop obstructions are torsion of a loop of small intestine around an adhesive band (Fig. 48.2), incarceration of the bowel in a hernia, volvulus of the cecum or colon, and development of an obstructing carcinoma of the colon with a competent ileocecal valve. The primary symptoms of a closed-loop obstruction of the small intestine are sudden, severe abdominal pain and vomiting, whereas symptoms of the large intestine are pain and sudden abdominal distention. This pain often occurs before associated findings of localized abdominal tenderness or involuntary guarding. When physical findings develop, there is a high level of suspicion that the viability of the bowel is compromised. When bowel obstruction is the most likely diagnosis, “abdominal pain out of proportion to physical findings” represents a surgical emergency.

Pathophysiology of Intestinal Obstruction

Local Effects of Bowel Obstruction. When a loop of bowel becomes obstructed, intestinal gas and fluid accumulate. Stasis of luminal content favors bacterial overgrowth, alters intestinal fluid transport properties and motility, and causes variations in intestinal perfusion and lymph flow. Luminal contents and volume, bacterial proliferation, and alterations in motility and perfusion work in concert to determine the rate at which symptoms and complications develop. Each of these factors merits discussion in some detail.

Intestinal Gas. Approximately 80% of the gas seen on plain abdominal radiographs is attributable to swallowed air.⁶

Approximately 70% of the gas in the obstructed gut is inert nitrogen.¹⁰ Oxygen accounts for 10% to 12%, CO₂ for 6% to 9%, hydrogen for 1%, methane for 1%, and hydrogen disulfide for 1% to 10%. In the setting of acute pain and anxiety, patients with intestinal obstruction may swallow excessive amounts of air. Passage of such swallowed air distally is prevented by nasogastric suction.

Intestinal Flora. An important contribution to normal digestive function comes from its bacterial population. In patients with normal gastric acid secretion, the chyme entering the duodenum is sterile. The small numbers of bacteria that are found in the stomach and proximal intestine are aerobic, gram-positive species found in the oropharynx. Distally, in the ileum and colon, gram-negative aerobes are present and anaerobic organisms predominate. Total bacterial counts in normal feces reach 10¹¹ organisms per gram of fecal matter. Control of the bacterial populations depends on intact motor activity of the intestines and the interactions of all species present. This ecology can be disturbed by antibiotic therapy or by surgical reconstructions that result in stasis within intestinal segments. Intestinal bacteria serve several functions, including metabolism of fecal sterols, releasing the small-chain fatty acids that are an important food source for colonocytes; metabolism of fecal bile acids, fat-soluble vitamins (e.g., vitamin K), and vitamin B₁₂; and breakdown of complex carbohydrates and organic matter, leading to formation of CO₂, H₂, and CH₄ gases.⁹ Considerable evidence suggests that the normal flora may contribute to baseline levels of intestinal secretion and, perhaps, normal intestinal motility. Under baseline conditions, the small intestines in germ-free animals are frequently dilated, fluid filled, and without peristalsis.^{11,12}

In recent years, the role of bacterial toxins in mediating the mucosal response to obstruction has received increasing attention. In germ-free dogs, luminal accumulation of fluid is not observed and absorption continues.¹² In addition, it is well recognized that bacterial endotoxins can stimulate secretion, possibly via release or potentiation of activity of neuroendocrine substances and prostaglandins.¹¹ Finally, since a substantial part of systemic microvascular and hemodynamic responses to endotoxemia appears to be attributable to heightened synthesis of nitric oxide,^{13,14} it seems likely that mucosal response to local inflammation and endotoxin release will also be altered by conditions modifying the synthesis or activity of nitric oxide. The role of nitric oxide in mucosal fluid and electrolyte movements is currently under active investigation.^{15,16}

Intestinal Fluid. Classical experimental studies established that fluid accumulates intraluminally with open- or closed-loop small-intestinal obstruction.^{9,17} Factors contributing to the accumulation of fluid include intraluminal distention and pressure, release of prosecretory and antiabsorptive hormones and paracrine substances, changes in mesenteric circulation, and elaboration and luminal release of bacterial toxins. Experimental studies and clinical investigation^{18,19} demonstrated that elevation of luminal pressures above 20 cm H₂O inhibits absorption and stimulates secretion of salt and water into the lumen proximal to an obstruction. In closed-loop obstructions, luminal pressures may exceed 50 cm H₂O and may account for a substantial proportion of luminal fluid accumulation.²⁰ In simple, open-loop obstructions, distention of the lumen by gas rarely leads to luminal pressures higher than 8 to 12 cm H₂O.²¹ Thus, in open-loop obstructions, the contributions of high luminal pressures to hypersecretion may not be important.

The release of endocrine/paracrine substances remains relatively uncharacterized in states of mechanical bowel obstruction.^{22,23} Suggestions have been made that vasoactive intestinal polypeptide (VIP) may be released from the submucosal and myenteric plexuses within the gut wall, promoting epithelial secretion and inhibiting absorption.²³ Use of prostaglandin

synthesis inhibitors has also implicated excess release of prostaglandins.²² Further work may be expected to focus on the role of luminal factors such as irritative bile acids, proinflammatory agents such as endotoxin and platelet-activating factor, and messengers such as nitric oxide in coordinating responses of mucosal secretory and absorptive functions during intestinal obstruction.

Intestinal Blood Flow. Microvascular responses to intestinal obstruction may also play an important role in determining the hydrostatic gradients for fluid transfer across the mucosa into the lumen. In response to heightened luminal pressure, total blood flow to the bowel wall may initially increase.²⁴ The breakdown of epithelial barrier structures and enzymatic breakdown of stagnant intestinal contents leads to increased osmolarity of luminal contents. In addition to secretory stimulation and absorptive inhibition of the mucosa, the simultaneous changes in hydrostatic and osmotic pressures on the blood and lumen sides of the mucosa favor flow of extracellular fluid into the lumen. Perfusion is then compromised as luminal pressures increase, bacteria invade, and inflammation leads to edema within the bowel wall.

Intestinal Motility. Obstruction of the intestinal lumen does not simply block distal passage of luminal contents. The accumulation of fluid and gas in the obstructed lumen also elicits changes in myoelectrical function of the gut, proximal and distal to the obstructed segment. In response to this distention, the obstructed segment itself may dilate, a process known as *receptive relaxation*.²⁵ Such changes ensure that, despite accumulation of air and fluid, intraluminal pressures do not amplify easily to the point of compromising blood flow to the intestinal mucosa. At sites proximal and distal to the obstruction, changes in myoelectrical activity are time dependent. Initially, there may be intense periods of activity and peristalsis. Subsequently, myoelectrical activity is diminished and the interdigestive migrating myoelectrical complex pattern is replaced by ineffectual and seemingly disorganized clusters of contractions.^{26–28} Similar alterations have been observed in experimental models of large-bowel obstruction. Subsequent patterns of myoelectrical quiescence may correspond to increasing accumulation of fluid and air proximally and the attempt to prevent luminal pressures from rising. It is likely that many factors contribute to the rate at which these changes in myoelectrical activity occur. These factors would include neurohumoral milieu, bacterial products, and luminal constituents.

Complications and Systemic Effects of Bowel Obstruction

Closed-loop Obstructions. The complications of closed-loop obstructions evolve rapidly. The reasons for this rapid evolution are best understood by considering the simplest and most common form of closed-loop obstruction, appendicitis. When a fecalith obstructs the blind-ended appendix, secretion of mucus and enhanced peristalsis represent the initial attempt to clear the blockage. Intense crampy abdominal pain focused at the umbilicus results. Nausea and vomiting are not uncommon as a result of luminal obstruction but as a reflexive response to hyperperistalsis and stretching of the mesentery. Over the next 8 to 18 hours, continued secretion of mucus to high intraluminal pressures, stasis, bacterial overgrowth, mucosal disruption, and elevation of luminal pressures convert intermittent cramps to constant and worsening pain. When luminal pressure exceeds mural venous pressure and then capillary perfusion pressures, inflammatory cells are recruited from surrounding peritoneal structures. This sequence of events leads to intense inflammation, release of exudate in the area of the appendix, and the first localization of pain from the umbilicus to the area of peritoneum lying nearest the inflamed appen-

dix. Peritoneal findings (localized tenderness, involuntary guarding, rebound or referred tenderness) and fevers appear. Subsequently, 20 to 24 hours into the illness, the blood supply of the appendix is compromised. Gangrene and perforation follow and, if not contained by surrounding structures, free perforation leads to a rigid abdomen. Toxins from necrotic tissue and bacterial overgrowth are released into the systemic circulation and shock ensues. Torsion of a loop of small intestine around an adhesive band or inside a hernia leads to a similar pattern of events. As discussed later, torsions of the large bowel are usually accompanied by massive distention of the loop by air and feces, but the compromise of intestinal wall perfusion and evolution into peritonitis, systemic toxicity, and shock are similar.

Open-loop Obstructions. Complications in open-loop obstructions do not necessarily evolve as rapidly as in closed-loop obstructions. Not uncommonly, an open-loop obstruction located in the proximal jejunum can be decompressed by the patient's ability to vomit. Proximal obstruction is characterized by vomiting and loss of gastric, pancreatic, and biliary secretions, with resulting electrolyte disturbances. These disturbances include dehydration, metabolic alkalosis, hypochloremia, hypokalemia, and usually hyponatremia. In contrast, obstructions of the distal ileum may lead only to a slowly progressing distention of the small intestine, with accommodation by intestinal myoelectrical function and minor alterations in fluid and electrolyte balances. Open-loop obstructions located in the midgut are often complicated by events similar to those seen in closed-loop obstructions or combinations of events seen in high and low obstructions (Table 48.2). Patients with distal jejunal obstruction tend to present with a combination of complications resulting from loss of intestinal contents from vomiting, as well as distention and compromise of intestinal wall perfusion.

Clinical Presentation and Differential Diagnosis

- 2 The four key symptoms associated with acute mechanical bowel obstruction are abdominal pain, vomiting, distention, and obstipation. Colon obstruction is usually accompanied by varying levels of pain with massive abdominal distention and obstipation. As noted earlier, the signs and symptoms of acute but simple small-intestinal obstructions are related to the level of the obstruction and the closed- or open-loop nature of the obstruction. Other abdominal conditions, such as appendicitis, diverticulitis, perforated peptic ulcer, cholecystitis, or choledocholithiasis, can usually be distinguished from small-bowel obstruction by clinical examination and basic laboratory data. It should be emphasized that bowel obstruction can complicate any of these abdominal conditions. The presence of another abdominal process does not exclude the complication of small-bowel obstruction.

Over the years, numerous attempts have been made to use groupings of clinical criteria to establish the diagnosis of complete and irreversible intestinal obstruction, as distinguished from partial intestinal obstruction that might improve without operative intervention or other abdominal pathology. In recent studies, computer-assisted analysis has been used to identify such criteria.²⁹ Key factors in the history and clinical examination include previous abdominal surgery, quality of pain (colic/intermittent vs. steady), abdominal distention, and hyperactivity of bowel sounds. Not surprisingly, the use of such computer-assisted algorithms confirms that the most important clues to the diagnosis of simple obstruction of the small intestine are obtained in a complete and careful history and physical examination. As discussed later, the role of plain abdominal radiographs and other imaging studies is to

confirm the clinical diagnosis of simple obstruction. It should be emphasized that, in simple obstruction, laboratory studies do not play a direct role in diagnosis, but aid in understanding the extent of complications such as dehydration, strangulation, and sepsis.

Strangulation obstruction is accompanied by symptoms and signs suggesting peritonitis, large fluid shifts, or systemic toxicity. These symptoms and signs include abdominal tenderness or involuntary guarding localizing to the area of the strangulated loop of bowel, decreasing urine output, fever, and tachycardia. There have been attempts to use common clinical and laboratory test criteria to identify the likelihood that the obstruction is associated with strangulation. Stewardson et al.³⁰ observed that the risk of strangulation was low in patients with partial (i.e., incomplete) or complete small-bowel obstruction if fever, tachycardia, localized abdominal tenderness, or leukocytosis were not present. These authors suggested that, in a setting consistent with bowel obstruction, any one of these four cardinal signs indicated a small risk for strangulation. The presence of any two of these signs increased the risk of strangulation so high as to warrant immediate surgery. These authorities and others have stressed, however, that when complete obstruction is present, no satisfactory clinical criteria are available to reliably exclude the possibility of strangulation.³⁰⁻³³

Different laboratory tests have been advocated for early detection of strangulated intestine. Metabolic (i.e., lactic) acidosis and increases in serum amylase, inorganic phosphate, hexosaminidase, intestinal fatty acid-binding protein, and serum D-lactate levels have all been associated with intestinal ischemia.^{34,35} Such laboratory abnormalities may be helpful in diagnosing established strangulation in a small group of patients where the diagnosis of necrotic bowel is not clear. However, a noninvasive and rapid test has not yet been developed that can provide information to suggest that tissue necrosis is imminent but not yet established.

Radiographs and Imaging

Plain Films. The role of plain abdominal radiographs and imaging studies is to confirm the diagnosis of bowel obstruction, locate the site of obstruction, and gain insight into the lesion responsible for the obstruction. On plain radiographs of the abdomen, the key findings of small-bowel obstruction reflect the accumulation of air and fluid proximal and clearance of fluid and air distal to the point of obstruction. Dilated loops of small intestine are defined as those greater than 3 cm in diameter. Free air represents perforation of a viscus and mandates immediate operation. Such findings include dilated loops of small bowel on the flat plate (Fig. 48.3) and multiple air-fluid levels located at different levels on the upright film or lateral decubitus film (Fig. 48.4). Based on these criteria, plain abdominal radiography is diagnostic in 67% to 80% of patients.^{36,37} In complete obstruction of the small intestine, the colon loops and rectum do not contain air. If there is air in the colon, the obstruction may be complete but early, or it may be incomplete.

In the colon, tight closed-loop obstructions (i.e., volvulus of the cecum, transverse colon, or sigmoid colon) are accompanied by distention of the obstructed segment (Fig. 48.5). The proximal colon is considered dilated when it reaches 8 to 10 cm; the sigmoid colon is considered dilated at 4 to 5 cm. In contrast, obstruction by carcinoma or diverticulitis presents with massive distention of the entire colon from the point of obstruction to the ileocecal valve. From this standpoint, any large-bowel obstruction may represent a “closed loop” as long as the ileocecal valve is competent. Although plain film findings can be used to differentiate obstruction of the small bowel from that of the large bowel, they are not accurate for localizing the specific site of obstruction.

A number of findings on plain films are highly suggestive of the nature of the offending lesion. These findings will be

FIGURE 48.3. Plain supine abdominal film of a patient with small-intestinal obstruction. Note the multiple dilated loops of small intestine (*black arrow*) in the left upper quadrant, characterized by complete markings of the plicae. Also note absence of air in colon and rectum.

discussed later in relation to specific causes of intestinal obstruction. One point needs to be stressed, however, and that is the appearance of plain films in the patient with a closed-loop obstruction of the small intestine. Such a loop of bowel may contain fluid and very little gas. Thus, in a plain film, it may not be visible or only barely visible as a minimally dilated “sentinel loop” that remains unchanged in position on films

FIGURE 48.4. Plain upright abdominal film of a patient with small-intestinal obstruction. Note the air-fluid levels in the stomach and multiple dilated loops of small intestine (*black arrows*), and absence of air in the colon or rectum.

FIGURE 48.5. Plain upright abdominal film of a patient with sigmoid volvulus. The dilated centrally located sigmoid loop is seen (arrowheads). The proximal colon is dilated and gas filled. (T, transverse colon; D, descending colon.)

that are performed in different projections. Because such patients generally present early after the onset of symptoms, the loops proximal to the closed loop will not have had time to fill with air and the remainder of the abdomen may appear gasless. In the setting of “abdominal pain out of proportion to physical findings,” a “normal” plain film does not exclude a closed-loop obstruction.

Contrast Studies. The diagnosis of bowel obstruction can generally be made by considering the clinical history, physical examination, laboratory, and plain radiograph findings. Contrast studies (i.e., small-bowel follow-through, enteroclysis, contrast enema) may provide specific localization of the point of obstruction and the nature of the underlying lesion. When obstruction of the small intestine is not progressing or resolving, a small-bowel follow-through may be performed to confirm the presence and location of the obstruction. Also, even under acute circumstances, diagnosis and management of colonic obstructions are generally enhanced by the use of a contrast enema. Under some circumstances, however, contrast studies are unnecessary and may be contraindicated. For example, in the classic setting of abdominal pain, nausea, vomiting, and a plain film indicating multiple air–fluid levels in the small intestine and colonic collapse, the diagnosis of acute obstruction can be made clinically. Failure to improve in a short period of time will mandate operation and contrast studies are unnecessary. When strangulation or perforations are strongly suspected, contrast studies are contraindicated.

The choice of contrast materials includes water-insoluble suspensions of barium and water-soluble agents such as Gastrografin or Hypaque. Barium studies provide the clearest images, in both small-bowel studies in which the contrast is given from above and colon/rectum studies in which the contrast is given by enema. If barium leaks into the peritoneum, it elicits intense peritonitis. If there is any possibility of bowel perforation or gangrene, barium should not be used. Water-soluble agents such as sodium amidotrizoate/meglumine amidotrizoate diatrizoate oral solution (Gastrografin) or diatrizoate sodium/diatrizoate meglumine (Hypaque) are hyperosmotic

and can elicit fluid translocation into the gut. When the obstruction of the small intestine is incomplete (as discussed later), the use of these agents may facilitate resolution. In two randomized trials, diagnostic and therapeutic use of water-soluble contrast agents such as Gastrografin reduced the need for operation by 74%.^{38,39} Gastrografin is hyperosmolar and causes mobilization of fluid into the bowel lumen and occasionally is therapeutic in cases of incomplete obstruction. Assalia et al.³⁸ divided 99 patients including 107 episodes of adhesive partial small-bowel obstruction into two groups: conservative management versus administration of 100 mL of Gastrografin via nasogastric tube. The group of patients who received Gastrografin had their first bowel movement, on average, in 6 hours versus 23 hours in the control group. Operative intervention was required in only 10% of the Gastrografin group (six episodes) compared with 21% (10 episodes) in the control group. The mean intervals of hospital stay were 2.2 days and 4.4 days, respectively. The authors suggested that orally administered Gastrografin is safe and therapeutic in adhesive partial small-bowel obstruction, though further studies were required to confirm the significance of the reduction in need for an operation.

Computed Tomography and Other Imaging Modalities.

The potential benefits of computed tomography (CT) scanning in diagnosis of bowel obstruction include the following^{40–42}: first, using dilute barium for luminal contrast, the obstructing segment may be localized and characterized as complete or incomplete. Second, the nature of the obstructing lesion, especially if it is malignant, can be established. Third, additional abdominal pathology (e.g., metastases, ascites, parenchymal liver abnormalities) may be identified. There is also evidence that, in special circumstances, CT may improve preoperative detection of strangulation.^{33,42} CT findings indicating the site of obstruction and impending ischemia include beaklike narrowing, mesenteric edema, vascular engorgement, and moderate to severe intestinal wall thickening (>2 mm) (Fig. 48.6). In addition, high attenuation of bowel wall on unenhanced CT scans, low or reduced attenuation of bowel wall on intravenous contrast CT scans, and presence of intramural air (pneumatosis) or portal venous gas are CT findings suggestive of strangulation. Attenuation reflects increased energy absorption, scattering, beam divergence, and other causes of energy loss. Thus, areas of high attenuation appear darker than areas of low attenuation.

It has also been suggested that real-time abdominal sonography could aid in the diagnosis of strangulation obstruction. In studies conducted in two different institutions, Ogata et al.^{43,44} demonstrated that the presence of significant amounts of peritoneal fluid and of an akinetic and dilated loop of bowel were strongly associated with the presence of strangulation. In patients who had strangulation but were thought to have simple obstruction only, these findings helped to make the preoperative diagnosis of infarction.

It should be emphasized that when the clinical picture suggests strangulation, unnecessary imaging studies should not delay resuscitation or expeditious movement to the operating room. Such studies will not necessarily be helpful when clinical criteria and basic abdominal radiographs have indicated the presence of a simple and complete obstruction. By itself, this diagnosis mandates urgent exploration and the information sought should be weighed against the risk of delay in going to the operating room. The message of the literature on imaging is not that the clinical picture can be misleading; in fact, in most studies evaluating the impact of imaging on diagnosis and timing of intervention, clinical diagnosis is seldom incorrect—it is highly specific when multiple clinical signs (tenderness, peritoneal signs, leukocytosis, profound dehydration) of strangulation are present. However, such a picture represents advanced disease and use of CT scan may detect strangulation before such signs are manifest. These findings

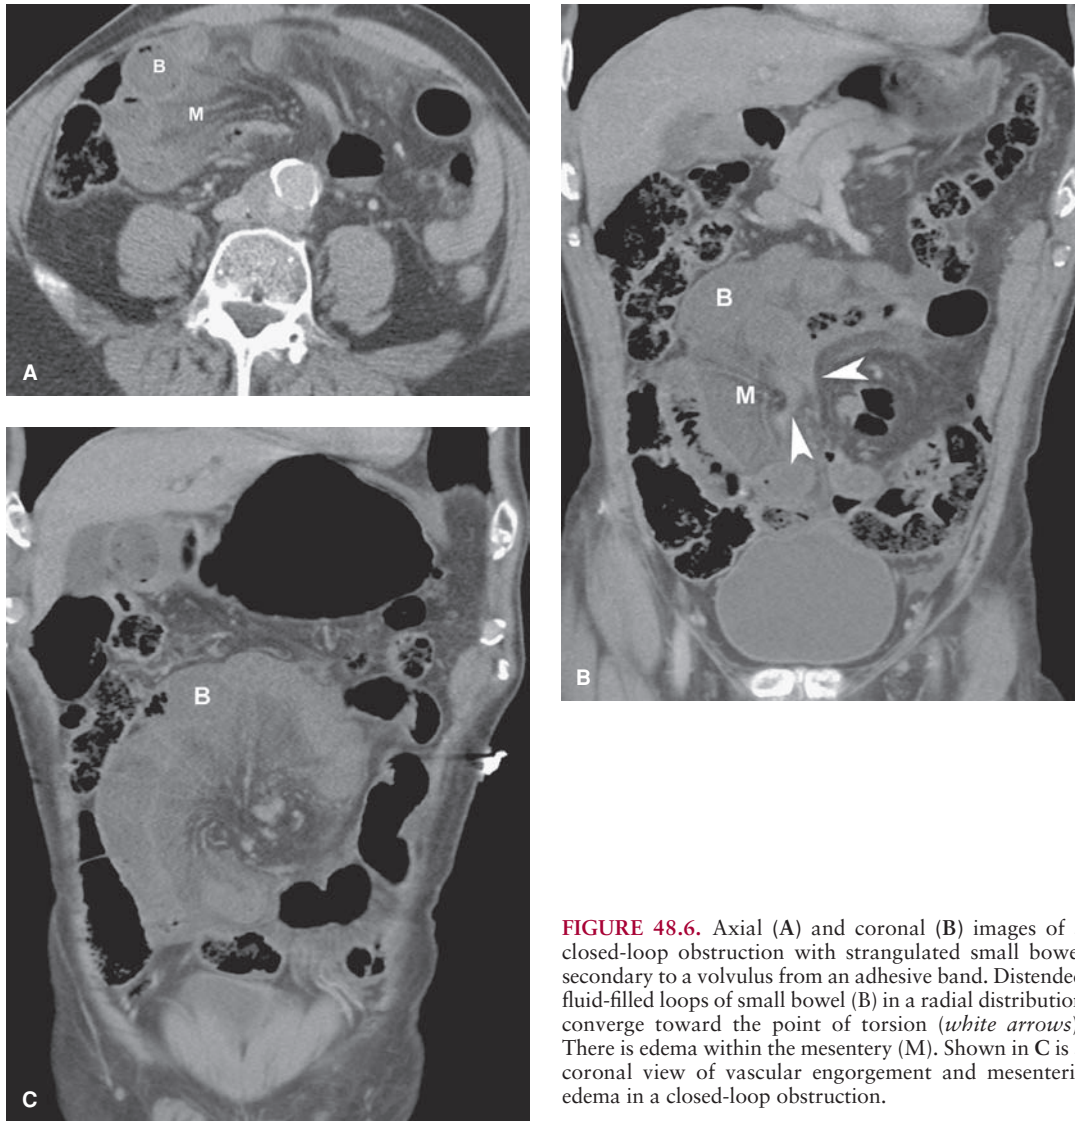

FIGURE 48.6. Axial (A) and coronal (B) images of a closed-loop obstruction with strangulated small bowel secondary to a volvulus from an adhesive band. Distended fluid-filled loops of small bowel (B) in a radial distribution converge toward the point of torsion (*white arrows*). There is edema within the mesentery (M). Shown in C is a coronal view of vascular engorgement and mesenteric edema in a closed-loop obstruction.

reinforce the dictum that when there are clinical signs of strangulation, surgery should be performed without additional imaging studies. In patients with equivocal findings or uncertain clinical diagnosis, CT can be highly useful in confirming the diagnosis, localizing the site, and detecting the cause of intestinal obstruction and strangulation.⁴²

General Considerations in Management of the Patient with Bowel Obstruction

Patients with obstruction of the large bowel present with abdominal pain, distention, and obstipation. Vomiting and electrolyte imbalances are sometimes prominent, though usually delayed. Elderly patients, in particular, are prone to dehydration. The presentation of small-bowel obstruction depends on level of obstruction, open- or closed-loop nature, and interval since onset of symptoms. Symptoms and signs of pain, vomiting, obstipation, and distention are present in variable degrees. The overall picture, however, is usually one of a patient with abdominal symptoms that are evolving and getting worse. In the settings described previously, the following questions must be addressed as expeditiously as possible.

1. *Is the abdominal pain disproportionate to the physical findings and laboratory studies?*

2. *How rapidly are the symptoms and signs evolving: minutes, hours, or less acutely?*
3. *Does the patient suffer from dehydration, electrolyte imbalance, and acid-base disturbance?*
4. *Is the obstruction complete or incomplete?*
5. *Is there a possibility of strangulation?*

Clinical data and basic laboratory studies will provide reliable information to answer the first three questions. Answering questions 4 and 5 will often depend on close clinical observation and reexamination in the first hours or days after presentation. Abdominal radiographs and imaging studies are frequently used to provide additional information to help answer these latter questions and to identify the obstructing lesion.

Summarized in Table 48.3 are thumbnail sketches of different, but typical, kinds of patients presenting with symptoms and signs consistent with obstruction of the small intestine. The principles of diagnosis and management of each of these patients begin with clinical information that indicates the likelihood of a bowel obstruction. Laboratory studies and plain abdominal films are used to confirm the diagnosis of obstruction and determine the extent of physiologic impairment. The patient's history and clinical course in the first few hours of observation are used to determine the likelihood of strangulation. Indications for surgery include rapid evolution of symptoms and signs and the diagnosis that the obstruction is complete. Contrast or imaging studies are used only when symptoms

TABLE 48.3**MANAGEMENT OF BOWEL OBSTRUCTION IN THREE HYPOTHETICAL PATIENTS**

	■ PATIENT I CLOSED-LOOP OBSTRUCTION	■ PATIENT II INTESTINAL OBSTRUCTION WITH STRANGULATION	■ PATIENT III OPEN-LOOP OBSTRUCTION OF THE DISTAL SMALL INTESTINE OR CECUM
Clinical:	Crampy periumbilical pain worsening over last 12 h. Two to three episodes of emesis. No distention, minimal flatus	Diffuse, crampy abdominal pain over 2 d with many episodes of vomiting. No bowel movements or flatus. T 100°F, P 100, dehydrated. Mild distention; local tenderness lower abdomen	Progressive abdominal distention over previous 2 wk. Mild discomfort. No vomiting. Few bowel movements and little flatus. Distention prominent, mild tenderness, no peritoneal findings
Lab:	No leukocytosis, pH, or electrolyte disturbances	WBC 16K. Serum Na ⁺ low, K ⁺ low, Cl ⁻ low, pH alkalotic	WBC normal, serum electrolytes mildly decreased
Radiography:	Nonspecific gas pattern on plain film	Multiple dilated loops and air–fluid levels. No gas in colon	Multiple dilated small bowel loops and air–fluid levels. Some gas and stool in proximal colon
Differential Dx:	Broad: includes appendicitis, closed-loop SBO, pancreatitis, nonsurgical conditions	Narrow: complete SBO likely, strangulation cannot be excluded	Narrow: distal small bowel or proximal colon obstruction likely, possibly incomplete
Initial Rx:	Admit with q3–4h reevaluation by clinical exam, WBC. Repeat films q8–12h. NG tube if vomiting persists. IVFs	Admit for rapid resuscitation with IVFs, IV antibiotics. Urinary catheter and NG intubation indicated	Admit for IVFs, NG intubation. Hypaque enema followed by barium to evaluate colon. CT if malignancy suspected
Indications for surgery:	If pain worsens, local tenderness or peritoneal signs evolve, WBC rises, urine output falls	Already present. Patient should be scheduled and brought to OR after adequate resuscitation (dramatic improvement with resuscitation may permit observation for 4 h)	Surgery performed when evaluation is complete or if clinical course deteriorates during evaluation
CT, computed tomography; Dx, diagnosis; IVF, intravenous fluids; NG, nasogastric; OR, operating room; P, pulse; T, temperature; SBO, small-bowel obstruction; WBC, white blood cell.			

are not evolving rapidly and when identification of the underlying lesion might alter the operative strategy (see specific lesions later).

The initial management of all patients with suspected bowel obstruction includes designating the patient “NPO” and starting intravenous fluids composed of isotonic Ringer or normal saline solutions. Restoration of fluid and electrolyte balance is a priority, often requiring frequent evaluation of serum electrolytes and pH. In rapidly evolving cases or patients with significant dehydration, an indwelling urinary catheter should be placed to monitor urine output. Invasive hemodynamic monitoring (e.g., a Swan-Ganz catheter) may be necessary to monitor the response to fluid resuscitation in patients with underlying cardiac, pulmonary, or renal insufficiency. Nasogastric decompression is indicated in most cases. The nasogastric tube, typically a 16- or 18-French sump tube, serves to prevent distal passage of swallowed air and minimizes the discomfort of refluxing intestinal content. The use of longer tubes has been advocated in certain settings, especially for patients with chronic but intermittent obstruction arising from Crohn disease, peritoneal carcinomatosis, radiation enteritis, or many previous laparotomies for obstruction. The underlying rationale is that advancement of the tip of the long tube to the obstructed loop would permit more effective decompression, perhaps resulting in relaxation of the loop and relief of the obstruction. Although this concept is appealing, there is no evidence to suggest a benefit for the use of a long tube in such settings.^{45,46}

The use of intravenous antibiotics in the initial management of bowel obstruction should be discussed as well. Clinically, it

has been recognized that antibiotics can ameliorate the evolution of symptoms and signs of strangulation in closed-loop obstruction and appendicitis. Studies in humans have demonstrated that, even in simple obstruction, bacterial counts in succus rise from under 10⁶ organisms/L to over 10⁹ organisms/L⁴⁷ and are not necessarily reduced with short-term administration of antibiotics.⁴⁸ Moreover, experimental studies indicate that bacteria can translocate across the intestinal mucosa, passing into lymph channels.⁴⁹ Further studies have demonstrated that germ-free animals can survive strangulation obstruction longer than normal animals and that luminal fluid taken from obstructed segments in germ-free animals is much less toxic than fluid taken from normal animals.^{50,51}

For all these reasons, it is a well-established practice to administer antibiotics perioperatively, in order to reduce wound infection and abdominal sepsis rates in patients undergoing operation to relieve intestinal obstruction, simple or strangulated. Once the decision has been made to proceed with surgery, broad-spectrum antibiotics, covering gram-negative aerobes and anaerobes, should be given. A second-generation cephalosporin or a combination of a first-generation cephalosporin and metronidazole is rational practice for perioperative coverage in both simple and strangulation obstruction. Nevertheless, the use of antibiotics in patients who have not yet been committed to operation has not been evaluated systematically. Giving antibiotics to patients who are being observed can obscure the underlying process and, in the end, delay optimal therapy.

The decision to perform abdominal exploration to relieve intestinal obstruction should be made expeditiously, but not in

the absence of critical information or before adequate resuscitation. Indications for surgery are outlined in Table 48.3, for each of the thumbnail vignettes. It should be emphasized that once a diagnosis of complete obstruction is made, simple or strangulated, the operation should proceed without undue delay. It is reasonable to commit the patient to a period of observation when the diagnosis is uncertain (i.e., there is a possibility of a nonsurgical diagnosis or that the obstruction is not complete). A practical point is that obstruction occurring in a patient without a previous history of laparotomy is not likely to be caused by peritoneal adhesions. This is known as *de novo* obstruction and, whatever the underlying cause, will not usually resolve without operation.

Specific Types of Bowel Obstruction

3 Chronic Adhesions. Peritoneal adhesions account for more than half of small-bowel obstruction cases. Lower abdominal procedures such as appendectomy, hysterectomy, colectomy, and abdominoperineal resection are common precursor operations to adhesive obstruction. Adhesions form after any abdominal procedure, however, including cholecystectomy, gastrectomy, and abdominal vascular procedures. In long-term follow-up, about 5% of patients undergoing laparotomy will develop adhesive obstruction; of these, 10% to 30% will suffer from additional episodes.^{52,53} Up to 80% episodes of small-bowel obstruction due to adhesions may resolve nonoperatively.^{30,31,38,45} However, an index episode and three recurrences indicate a likelihood of over 80% that there will be more recurrences.⁵² Surgical management of an acute episode appears to reduce subsequent recurrence rates from ~15% to ~6%,⁵³ but no studies have been able to establish whether the immediate benefit of laparotomy for any given episode of simple adhesive obstruction outweighs the overall benefit of expectant management and operation only for serial recurrences. Thus, a previous history of a laparotomy simply provides a reasonable basis for expectant management of patients in whom it is not yet possible to diagnose a complete obstruction. Ultimately, patients who present with signs and symptoms from bowel obstruction are managed according to the CT findings and clinical course.

The pathobiology of adhesion formation has been the subject of considerable investigation. Histologic examination of chronic adhesions reveals foreign body reaction, usually to talc, starch, lint, intestinal content, or suture. Talc and starch are found less commonly now than previously, because of improvements in techniques of manufacture and sterilization of surgical gloves. Mesothelial cells are the presumed origin of tissue plasminogen activator (TPA). TPA binds fibrin and plasminogen, thereby preventing adhesion formation. In early studies, inflammatory cells, including mast cells,⁵⁴ were implicated in the process that produces adhesions. Recent studies^{55,56} have emphasized the role of various cytokines in exacerbating or inhibiting adhesion formation in different animal models. Biologically active substances that might prove useful in preventing postoperative adhesions include transforming growth factor- β (TGF- β) and vascular endothelial growth factor (VEGF), both of which may be targeted for inhibition with less fear of compromising the response to bacterial infection.^{55,56}

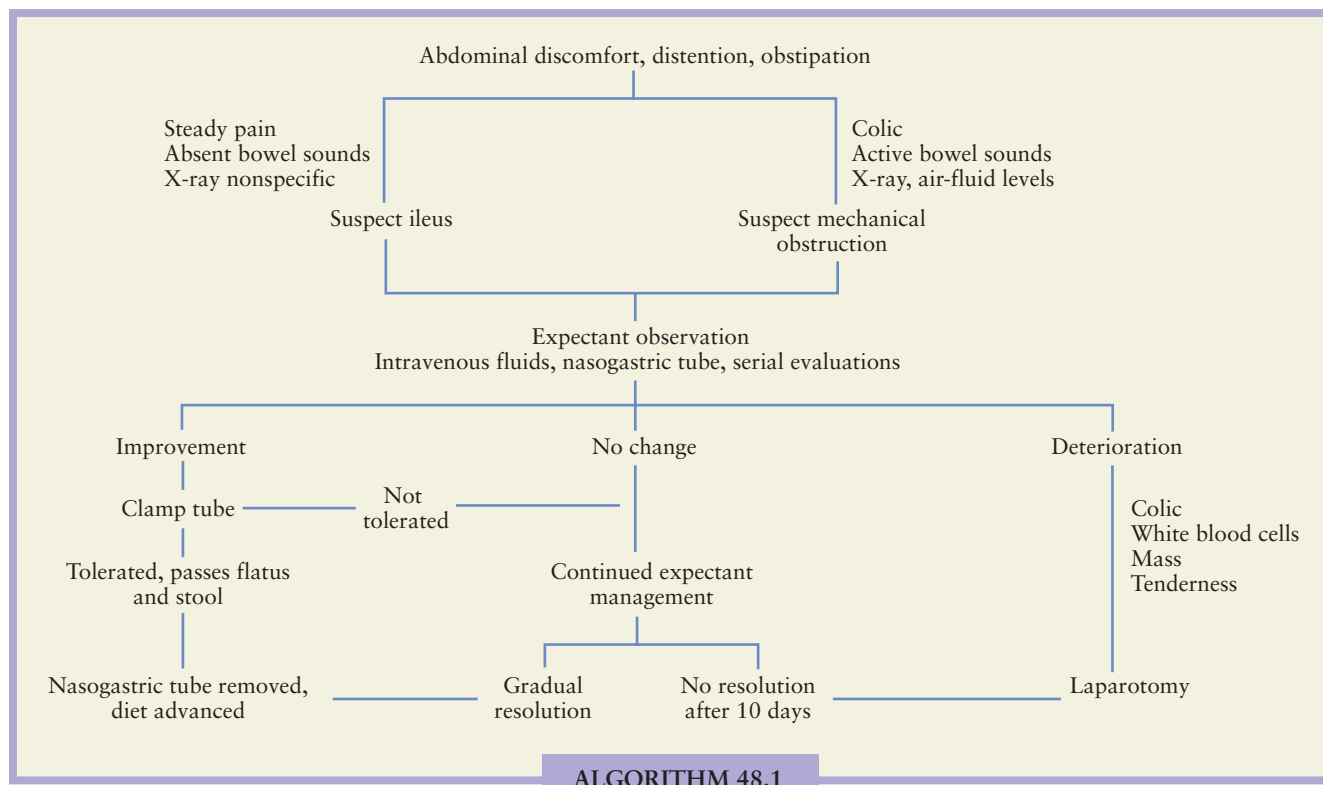

Current strategies to prevent adhesions after a first laparotomy include targeting the fibrinolytic system, which enhances rapid healing and appears to minimize formation of peritoneal adhesions.⁵⁵ Attempts to minimize or prevent adhesion formation have resulted in development of a hyaluronic acid-carboxymethylcellulose membrane (Seprafilm, Genzyme, Cambridge, MA). This compound mechanically prevents adhesion formation by physically separating adjoining tissues. It is absorbed by the body in 7 days and thus is present only during the phase of fibrosis, and not as a persistent foreign body. Randomized trials have suggested that this compound prevents,

minimizes severity, and decreases density and vascularity of adhesions.^{55,57} Other trials corroborate decreased severity, density, and vascularity of adhesions but not total prevention of adhesions or reduction of the incidence of subsequent bowel obstruction.⁵⁸ Seprafilm and similar barriers have been advocated for use in patients in whom a second abdominal procedure is planned or significant adhesions anticipated (e.g., Hartmann procedure, ileal pouch anal anastomosis with protecting ileostomy, pelvic surgery, gynecologic procedures, and colon surgery), though it has been proposed for all surgeries by the manufacturers. Meta-analyses in gynecologic procedures support claims that numbers and density of adhesions are reduced, without necessarily improving the incidence of subsequent intestinal obstruction.

More important than pharmacologic approaches, however, are the efforts of the surgeon to pay meticulous attention to hemostasis and surgical technique, and to carefully inspect for and remove foreign material from the peritoneal cavity. It is also possible that the use of monofilament sutures for fascial closure and avoidance of closure of the peritoneum as a separate layer may lower the formation of adhesions between viscera and the abdominal wall.⁵⁹

Early Postoperative Adhesions. Obstruction in the immediate period following abdominal surgery is uncommon but may occur in up to 1% of patients in the 4 weeks following laparotomy. Adhesions are responsible for approximately 90% of such cases and hernias for approximately 7%.⁶⁰ Intussusception, abscess, or technical errors may be responsible for the remainder of cases.^{61,62} Most cases occur after surgery of the colon, especially abdominoperineal resections, or operations in the lower abdomen. It is rare for upper abdominal surgery to cause such obstructions. A common scenario is that a patient will undergo colectomy uneventfully, pass flatus, and have bowel sounds by postoperative day 3. On the fourth postoperative day the patient suddenly becomes distended and uncomfortable, and stops passing flatus and stool. Patients with acutely evolving symptoms and signs represent complete obstruction and should be managed as such. In this latter setting, the mortality may be as high as 15% due to delays in recognition and operative intervention. The loss of bowel sounds after a short period of normal or hyperactive activity is worrisome for ischemia of the obstructed segment. The vast majority of such cases may be treated as partial intestinal obstruction; nasogastric suction and intravenous fluids will help resolve symptoms within a few days (Algorithm 48.1). When the clinical course does not demand earlier intervention, a nonoperative approach may be tried for 10 to 14 days and will resolve the obstruction in over 75% of such cases.^{60,62,63}

Hernia. Hernias of all types are second only to adhesions as the most frequent causes of obstruction in western countries. External hernias such as inguinal (Fig. 48.7) or femoral hernias may present with the symptoms of obstruction and will not be diagnosed unless sought.⁶⁴ Femoral hernias are particularly prone to incarceration and bowel necrosis due to the small size of the hernia inlet.⁶⁴ Other hernias such as umbilical, incisional, paracolostomy, or lumbar hernias are obvious. Still others such as internal hernias are usually diagnosed at laparotomy for obstruction. These include obturator hernias, paraduodenal hernias (Fig. 48.8), and hernias through the foramen of Winslow or mesenteries. When hernia has been identified as the cause of the obstruction, the patient is quickly resuscitated, given antibiotics, and taken to the operating room. The hernia is then reduced and the viability of the bowel assessed. If viable, the bowel is left alone; if not, it is resected. The hernia defect is then repaired. One important consideration is the Richter hernia (Fig. 48.9).⁶⁵ In this variant, only a portion of the wall of the bowel is incarcerated and thus incarceration and strangulation may not be associated with complete obstruction. These most frequently occur in association with femoral or inguinal hernias. Complete obstruction can occur if more than half of the bowel circumference is incarcerated.

ALGORITHM 48.1. Approach to recognition and management of early postlaparotomy obstruction of the small intestine. (Adapted from Welch JP. *Bowel Obstruction: Differential Diagnosis and Clinical Management*. Philadelphia, PA: WB Saunders; 1989.)

For external (abdominal wall) hernias, it may be possible to perform *taxis*, that is, the manual reduction of an incarcerated/irreducible hernia. Taxis is usually successful in reduction of an irreducible hernia. Occasionally, taxis results in reduction of the contents of the hernia sac en mass (still obstructed), reduction of strangulated bowel resulting in generalized peritonitis, or reduction of an obstructed Richter hernia. This is one reason for using circumsection in relying on taxis as a mode of treatment for

incarcerated inguinal, femoral, and incisional hernias. In general, taxis should be followed expeditiously by operative repair.

Gallstone Ileus. As a result of intense inflammation surrounding a gallstone, a fistula may develop between the biliary tree and the small or large intestine. Most fistulas develop between the gallbladder fundus and duodenum. If the stone is greater than 2.5 cm in diameter, it can lodge in the narrowest

FIGURE 48.7. Computed tomography images of an inguinal hernia. Axial (A) and coronal CT scan (B) images showing incarcerated right inguinal hernia with air and fluid filled loop of small bowel (arrowhead) in the right inguinal canal (arrow) causing small bowel obstruction with dilated loops of proximal small bowel (B).

FIGURE 48.8. Paraduodenal hernia. A: Plain film of closed-loop obstruction with neck of the closed loop in the right upper abdomen. B: Computed tomography scan showing slippage of the jejunum behind the stomach, with dilatation and obstruction of the duodenum. Baltimore: Williams and Wilkins; 1994:131–149.)

portion of the terminal ileum, which is just proximal to the ileocecal valve. This complication is rare, accounting for less than 6 in 1,000 cases of cholelithiasis and no more than 3% of cases of intestinal obstruction. Typically, the patient is elderly and presents with intermittent symptoms over several days, as the stone

tumbles distally toward the ileum. The classic findings on plain radiographs include those of intestinal obstruction, a stone lying outside the right upper quadrant, and air in the biliary tree (Fig. 48.10). Treatment includes removal of the stone and resection of the obstructed segment only if there is evidence of tissue

FIGURE 48.9. Richter hernia. A: Computed tomography scan showing contrast and air in the incarcerated segment within the left groin. B: Schematic diagram showing Richter hernia, in which the antimesenteric border (but not the whole wall) of the intestine is incarcerated.

FIGURE 48.10. A: Plain radiograph of a patient with gallstone ileus, showing obstructed loops of small intestine (*black arrow*) in the abdomen and a gallstone (*white arrow*) in the pelvis (gallstone was initially misinterpreted as an EKG lead [*black arrow*]). B: Computed tomography (CT) scan showing a cholecystoduodenal fistula (*black arrow*) with air in the biliary tree (D, duodenum). C: CT scan showing gallstone (*white arrow*) in the distal ileum and fecalization of luminal content adjacent to the stone.

necrosis. The risk of a recurrent gallstone ileus is about 5% to 10%.^{66,67} Such recurrences usually occur within 30 days of the initial episode and are usually due to stones in the small intestine that were missed at the original operation.

The difficult decisions in management of gallstone ileus focus on the fistula. The arguments in favor of disconnecting the fistula and removing the gallbladder have been the possibility of recurrence of gallstone ileus and the risk of cholangitis due to reflux of intestinal content into the biliary tree. When the latter operation is included, the mortality may be doubled as compared to simple removal of the gallstone. It is used selectively in good-risk patients. The long-term incidence of biliary tract infections has not been common enough to warrant the more aggressive approach at the initial operation. Some authors have advocated cholecystectomy at a second operation, especially if the patient is young and fit. The consensus is that cholecystectomy should not be performed at the initial operation for gallstone ileus, except in highly selected patients. A careful search of the entire intestine should be performed to exclude the possibility of additional large stones.^{66,67}

Intussusception. About 5% of intussusceptions occur in adults. An intussusception occurs when one segment of bowel telescopes into an adjacent segment, resulting in obstruction and ischemic injury to the intussuscepting segment (Fig. 48.11), and the obstruction may become complete, particularly if tissue inflammation and necrosis occur. Of adult cases, 90% are associated with pathologic processes.^{68,69} Tumors, benign or malignant, act as the lead point of intussusception in more than 65% of adult cases. A significant proportion of cases have been reported to occur

after abdominal surgery for lesions other than neoplasm. In cases not associated with neoplasm, Sarr et al.⁶⁹ reported that approximately 20% were related to the suture line, approximately 30% to adhesions, and approximately 60% to intestinal tubes. Intussusception related to long tubes can occur when the tube is withdrawn, but most frequently occurs with the tube in place. Perioperative intussusception frequently subsides without intervention.

Four types of intussusception are recognized: enteric (Fig. 48.12), ileocolic, ileocecal, and colonic. In the ileocolic form, the ileum telescopes into the colon past a fixed ileocecal valve. In the ileocecal form, the valve itself may be the lead point of the intussusception. Radiographic features of intussusception are not specific. Plain films reveal evidence of partial or complete obstruction. Occasionally, a sausage-shaped soft tissue density will be seen, outlined by two strips of air. Recently, in both pediatric and adult cases, it has been suggested that sonography may be useful in diagnosis. Nevertheless, the mainstays of diagnosis are contrast studies or CT scan. Because of the high incidence of tumors, surgery has generally been recommended. Reduction by hydrostatic pressure, which is the standard of care in pediatric cases, is not usually attempted in adults. Clear indications for operation include long length and wide diameter of the intussusception, presence of a lead point, or evidence of bowel obstruction.⁶⁸ Recent studies have called into question the need to operate in all cases detected on sensitive imaging studies such as CT scan, arguing that a number of these patients can be safely managed without operation.⁶⁸ However, in the opinion of these authors, it is difficult to advise expectant management except in unusual circumstances.

FIGURE 48.11. Anatomy of intussusception. The intussusceptum is the segment of bowel that invaginates into the intussusciens.

Crohn Disease. Indications for surgery in Crohn disease are discussed elsewhere in this book. In this disease, obstruction occurs under two different sets of circumstances.⁷⁰ When the disease has flared acutely, the lumen may be narrowed by a reversible inflammatory process. The result is an open-loop

obstruction that may respond first to intravenous hydration and nasogastric decompression, and ultimately to therapy with corticosteroids or other anti-inflammatory regimens. Alternatively, obstruction may occur in the setting of a chronic stricture. Such strictures will not respond to conservative measures and, once diagnosed, operative therapy should not be delayed. One important clinical point is that about 7% of strictures in the colon, and an uncertain proportion of those in the small intestine, are malignant.⁷⁰ Extent of resection is thus based on intraoperative findings, that is, to margins beyond visibly diseased bowel and not necessarily including enlarged lymph nodes in the mesentery. If there is suspicion for malignancy, a lymphadenectomy is performed.

A second clinical point is that Crohn-affected bowel may not be dilated proximal to the obstruction but can be complicated by a small perforation. Such a microperforation may not be large enough to be associated with free air on plain films. The patient may thus present with significant abdominal pain and tenderness. A CT scan is likely to be the most sensitive imaging modality for obtaining evidence that differentiates conditions that require immediate surgery (closed-loop obstruction, microperforation) from simple obstruction that would otherwise be observed. In the absence of clinical progression of symptoms and signs, however, extended conservative management is warranted before the patient is committed to surgery.

Malignant Obstruction. Obstruction can complicate malignancies of the small and large bowel in a number of settings. Studies have documented that 10% to 28% of patients with colorectal cancer and 20% to 50% of patients with ovarian cancer will present with a malignant bowel obstruction at some point during the course of their disease.⁷¹ Most commonly, a primary lesion such as an adenocarcinoma or lymphoma will enlarge until the lumen of the intestine is blocked. The lesion then presents with symptoms and signs associated with the level of obstruction and is managed accordingly.

A second setting involves a patient who previously has undergone surgery for malignancy and now returns with evidence of bowel obstruction. The likelihood that the obstruction is due to recurrent disease is based on several factors,

FIGURE 48.12. Axial (A) and coronal CT scan (B) images of an ileocolic intussusception secondary to colon carcinoma (M) as a lead point. Intussusceptum (long arrows) and intussusciens (arrowhead). Mesenteric vessels and fat (white arrowhead) accompany the intussusceptum.

FIGURE 48.13. Significant palliation can be achieved in a patient with obstructing but unresectable malignancy. Enteroenterostomy is performed to bypass the obstructing segment.

including the origin of the primary malignancy, the stage of the primary malignancy, and the designation of the original surgery as curative or palliative. Gastric and pancreatic carcinomas often present with or are subsequently complicated by peritoneal carcinomatosis and thus the subsequent obstruction is most likely due to malignancy. With respect to colon and rectal carcinomas, as many as 50% of cases presenting with obstruction after resection of the primary malignancy may be due to adhesions and not recurrent malignancy.^{71,72} In addition, even if the obstruction is due to now unresectable disease, significant palliation can be obtained through bypass or enterostomy in up to 75% of patients (Fig. 48.13). However, the underlying diagnosis of cancer in this patient population mandates careful attention be paid to patient selection prior to any surgical intervention and risk factors for poor outcome (Table 48.4, Algorithm 48.2). In patients presenting with gastroduodenal and colorectal obstructing lesions who are not candidates for surgical bypass or enterostomy, endoscopic management options including percutaneous endoscopic gastrostomy tube (PEG) placement and self-expanding metallic stent (SEMS) placement are available (Algorithm 48.2). These options have been associated with symptomatic relief in more than 75% of patients.⁷¹

Management of incurable malignant obstruction may require an approach that moves away from classical surgical teaching of nothing by mouth, nasogastric tube, intravenous fluids, and serial radiographs.⁷³ Patients with advanced malignant obstruction in the absence of a solitary or correctable obstructing lesion are generally managed without surgery (Algorithm 48.2). Patients are managed without a nasogastric

tube if possible. They are encouraged to eat as soon as obstructive symptoms resolve using a low-fiber diet. Antiemetics and opioids via continuous subcutaneous infusions are used to manage nausea and vomiting and colic, respectively. In addition, octreotide, a somatostatin analogue, is used in palliation of refractory malignant intestinal obstruction by improving intestinal mucosal absorption, improving motility, reducing gastrointestinal hormone levels and intestinal secretions, and having a direct antineoplastic effect on the obstructing tumor.⁷⁴ This allows true palliative care outside a hospital setting saving patients the pain, discomfort, and complications of hospitalization and unproductive surgery.⁷³

Volvulus. The term *volvulus* indicates that a loop of bowel is twisted more than 180 degrees about the axis of its mesentery. Volvulus has been reported for the cecum, transverse colon, splenic flexure, and sigmoid colon. A special variant of volvulus, complicating a condition known as *Chilaiditi syndrome*, can occur when redundant loops of the transverse colon slip between the liver and diaphragm and then torse.⁷⁵ Generally, the condition is asymptomatic, but when associated with volvulus it must be relieved surgically.

The most common site for volvulus is the sigmoid colon, accounting for 65% of cases.⁷⁶ By definition, a volvulus is a form of closed-loop obstruction of the colon. Air is always present in the colon and rectum, and thus volvulus of any segment of the colon is associated with abdominal distention and, usually, severe abdominal pain. As shown in Figure 48.5, the most common radiographic feature is the “bent inner tube” appearance of the sigmoid, which is located in the upper abdomen. The preferred method of management involves endoscopic decompression. A rigid or flexible proctosigmoidoscope is advanced gently into the rectum until a rush of air and feces indicate that the loop has been untorsed. A rectal tube is then advanced well into the loop as a stent to prevent retorsion. Gangrene of the colon does not usually complicate the picture if the patient is seen and treated promptly. This conservative approach resolves the volvulus in 85% to 90% of cases and elective resection or fixation of the redundant segment can then be planned. Following endoscopic decompression, recurrence of the volvulus is higher than 60%.⁷⁷ Thus, an operation to remove the sigmoid should be performed if the patient is fit for surgery.⁷⁸ However, a majority of these patients are elderly and infirm and approximately 15% have a history of psychiatric disorder. As a result, the patient may present with peritoneal findings, sepsis, and shock. In this setting, rapid resuscitation followed by urgent resection and colostomy is warranted. Other forms of volvulus generally cannot be detorsed without operation. Fixation of the torsed segment (e.g., via cecostomy or cecopexy) is generally a less satisfactory solution than resection of the involved segment and is not generally recommended.⁷⁶

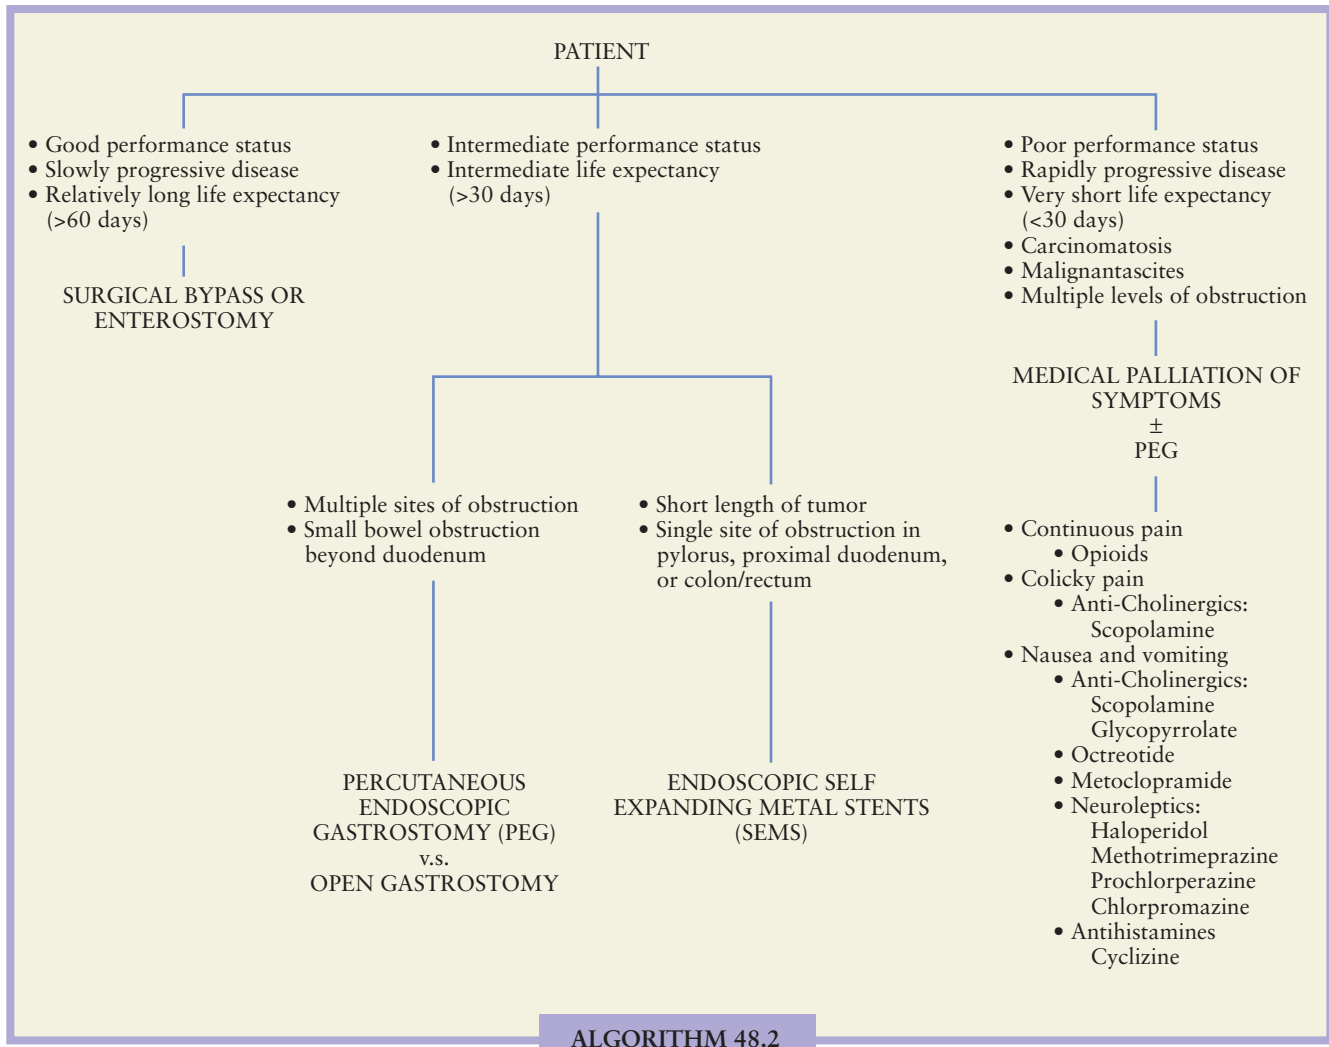

TABLE 48.4

RISK FACTORS FOR UNFAVORABLE OUTCOME IN MALIGNANT OBSTRUCTIONS

Advanced age (biologic/physiologic)
Poor performance status
Advanced stage of primary malignancy (previous treatments, availability of anticancer options, life expectancy)
Malnutrition/cachexia
Comorbidities
Absence of psychosocial support
Ascites (>100 mL associated with poor outcome)
Single vs. multiple sites of obstruction
Carcinomatosis (believed to respond poorly to surgical intervention)

Radiation Enteritis. After asymptomatic periods lasting at least 10 years, chronic intestinal obstruction can result. Radiation injury elicits an underlying vasculitis and fibrosis that lead to chronic, recurring low-grade partial obstruction of the small intestine or stricturing and bleeding in the colon and rectum. Operation is indicated for incapacitating symptoms and obstruction not resolved by conservative management.⁷⁹ Recurrence of the original tumor as a cause of obstruction should be considered and excluded. However, the diffuse nature of the injury and pathologic responses can lead to massive resections that leave the patient with short-bowel syndrome. Attempts to suture scarred loops can also result in chronic inflammation and formation of interloop abscesses and fistulas. The incidence of suture line leak is high.⁸⁰

Role of Laparoscopy in Management of Small-bowel Obstruction. Since the advent of laparoscopically assisted techniques for general abdominal surgery, a number of investigators have reported the feasibility of laparoscopic approaches

ALGORITHM 48.2. Algorithm for management of malignant obstruction. (Contributed by William Peranteau, M.D.)

to small- and large-bowel obstruction. Such approaches have been used, with varying degrees of success, to manage obstruction from a number of different etiologies (Table 48.5).^{81–83} Laparoscopic management of bowel obstruction provides many potential benefits including quicker recovery of bowel function, shorter hospital stay, and fewer postoperative complications including a decreased incidence of wound infection and pneumonia. Additionally, as suggested by both clinical and experimental studies in animal models, laparoscopy is associated with less postoperative adhesion formation than open surgery.⁸⁴ Thus, laparoscopic management of bowel obstruction may result in a decreased lifetime risk for recurrent bowel obstruction. An appealing hypothesis, this long-term benefit of laparoscopic surgery has not yet been proven clinically.

In adults, the most common etiology for which laparoscopic versus open surgical management of bowel obstruction has been evaluated is adhesive bowel obstruction.^{83,85–94} Studies of laparoscopic lysis of adhesions for small-bowel obstruction indicate that it is feasible, with acceptable operative times, length of hospital stay, and conversion and complication rates (Table 48.6). Studies directly comparing laparoscopic to open surgical management of adhesive small-bowel obstruction highlight the benefits of the laparoscopic approach as indicated by statistically significant decreases in complication

rates, time to return of bowel function, length of hospital stay, and even overall cost (Table 48.7).

Despite these benefits, laparoscopic management of bowel obstruction should be approached with caution and individualized to specific clinical situations.⁹⁵ Laparoscopy is discouraged when the surgeon is uncomfortable with the technique or in patients presenting with peritonitis, hemodynamic instabil-

ity, severe comorbid conditions, or complete and distal obstruction, or when contraindications to pneumoperitoneum exist. The selective use of laparoscopy is supported in the management of intussusception by a recent review by the French Study Group for Pediatric Laparoscopy, which found a statistically significant risk of conversion to an open procedure in patients with peritonitis at presentation, increased length of

time between the onset of symptoms and diagnosis (1.6 vs. 3.1 days), and the presence of a pathologic lead point.⁹⁶ Although these early retrospective studies are encouraging, prospective studies evaluating laparoscopic management of small-bowel obstruction are required to definitively document its benefits over the traditional open approach.

ILEUS AND PSEUDO-OBSTRUCTION

Ileus

4 Etiologic Factors. An ileus or *eileos* (Greek for “twisting”) reflects a loss of forward peristalsis and coordination of the motility of the different regions of the gastrointestinal tract. A functional obstruction results.⁹⁷ Clinically, bowel sounds, passage of flatus, and bowel movements have been used to signal the return of bowel function and coordination of peristalsis. Liquid contrast and radiolabeled marker studies suggest that effective duration of ileus varies in different regions of the alimentary tract.^{98,99} A postoperative ileus (POI) may last for 0 to 24 hours in the small intestine, 24 to 48 hours in the stomach, and 48 to 72 hours in the large bowel.^{100,101} The type of surgery and the wide variety of endpoints used to measure gut recovery often decide the duration of ileus. There is no consensus as to which one is most clinically meaningful. Duration of ileus is therefore primarily dependent on the return of colonic motility and its coordination with other regions of the gastrointestinal tract. A typical period of ileus is thus self-limited and easily tolerated. Factors implicated in ileus (Table 48.6) are outlined in the following sections.

Neurohumoral Peptides. Increases in endogenous opioid release and other peptides such as calcitonin gene-related peptide, motilin, substance P, VIP, and substance P have all been established as inhibitory neurotransmitters in the intrinsic gut nervous system. Antagonists to VIP, substance P, and inhibitors of nitric oxide (NO) synthesis improve postoperative bowel motility.^{102,103} Calcitonin gene-related peptide inhibits postoperative gastric emptying and gastrointestinal transit.^{104,105} The use of anticholinergic medications delays recovery of an ileus.¹⁰⁶

One group of neurohumoral substances that are particularly important in this regard are the opioids, both synthetic and endogenous. Opioids are established neurotransmitters in the central and peripheral nervous systems, and it is well established that their use delays gastric emptying and promotes nonpropulsive smooth muscle contraction with an increase in intraluminal pressure throughout the entire gastrointestinal tract.^{107,108} Over the years, a series of experimental studies have indicated that recovery of ileus is accelerated during administration of specific antagonists to κ or μ opioid receptors,^{109,110} suggesting that endogenous opioid release modulates recovery from ileus.

Inflammation. A relatively recent series of experimental and clinical investigations have focused attention on the role of inflammatory cells and mediators of inflammation in the development of prolonged ileus. Surgical intervention results in elevated levels of interleukin-6 (IL-6), cyclooxygenase-2 (COX-2), and inducible nitric oxide synthetase (iNOS), all mediators of inflammation from macrophages.^{111,112} In experimental animals, focal manipulation of the bowel may result in a panenteric inflammation and ileus.¹¹² In experimental animals and human subjects, activated macrophages have been found in the muscularis of the small bowel as early as 3 hours after laparotomy.¹¹³ Increased COX-2 expression leads to prostaglandin release. Jejunal contractility appears to be impaired, an effect blocked in COX-2 knockout mice and by the administration of selective COX-2 inhibitors. In related studies both in experimental animals and human subjects, Kalff et al.¹¹³ found that NO synthe-

sis is stimulated in activated macrophages in the muscular layer of the small intestine following surgical intervention. More recently, degranulation of mast cells has also been implicated in the pathogenesis of ileus after laparotomy,^{114,115} with mast cell destabilizers having been shown to prevent mechanically induced intestinal inflammation and dysmotility.

Inhibitory Neural Reflexes. Noxious spinal afferent signals are thought to increase inhibitory sympathetic activity in the gastrointestinal tract.¹¹⁶ Blockade of spinal afferents with epidural local anesthetics or with topical capsaicin has been shown to accelerate resolution of ileus in experimental studies.^{104,105} In clinical studies of patients undergoing complex abdominal operations through conventional laparotomy incisions, it appears that conventional intramuscular injections are less likely to be associated with prolonged ileus than strategies utilizing patient-controlled intravenous injection.^{117,118} Moreover, utilization of epidural analgesia tends to decrease recovery times from ileus in this group of patients,^{119–121} suggesting that autonomic pathways coursing through the spinal cord may serve as control points for ileus.

Central responses have also been observed as a result of laparotomy¹¹⁶ and have been linked to activation of afferent pathways in the vagus nerve and a general response of the organism to stress and release of corticotrophin-releasing factor.¹²² Very recently, the efferent pathways in the vagus have also been implicated as possible modulators or control points for the inflammatory response. A series of experimental studies^{123,124} has suggested that the vagus participates in suppression of certain macrophage activities, leading to earlier resolution of intestinal ileus.¹²⁴ These observations offer the possibility of a multidimensional understanding of ileus, both in individuals who are recuperating normally and in those who are not and have no specific risk factors for protracted ileus (e.g., undrained sepsis, overuse of narcotics, spinal cord injury, severe pelvic fractures, and retroperitoneal inflammation).

5 Diagnosis. It is important to distinguish between a normal *postoperative ileus* and a *paralytic ileus*. The distinction is predominantly one of time since operation and based on circumstance. Postoperative ileus is less severe, self-limiting (lasts 2 to 3 days vs. 3 to 5 days), and usually an indicator of colonic dysmotility, whereas a paralytic ileus represents inhibition of small-bowel activity. A prolonged POI (PPOI) occurs with protracted signs or symptoms of abdominal distention, bloating, diffuse and persistent abdominal pain, nausea, vomiting, and an inability to pass flatus or tolerate an oral diet.

It is also important to distinguish between a PPOI from a mechanical small-bowel obstruction (SBO). Clinically, the presence of intense colicky pain, feculent emesis, or rapidly progressing pain or distention is more suggestive of SBO than PPOI. Localized tenderness, fever, tachycardia, and peritoneal signs suggest bowel ischemia or perforation, necessitating emergent surgical intervention.¹⁰

A variety of clinical circumstances and laboratory tests may also increase suspicion for prolonged ileus and lessen concern for mechanical obstruction and associated complications. In addition to opiates, a number of medications have been associated with slow recovery of intestinal motor function (Table 48.8). Isolated metabolic disturbances such as ketoacidosis, hypomagnesemia, hypercalcemia, and hypokalemia can prolong ileus. Ileus can be caused and perpetuated by systemic inflammatory responses to sepsis, abscess, and pancreatitis.

When the patient's postoperative ileus has extended beyond the expected period, plain films of the abdomen reveal gas in segments of both small and large bowel (Fig. 48.14). At this point, the patient may begin to experience some discomfort and distention, as swallowed air fills loops that do not have effective peristalsis. Bowel sounds may be present, if hypoactive. The differential diagnosis now includes the possibility of mechanical obstruction from early postoperative adhesions

TABLE 48.8**FACTORS CONTRIBUTING TO PROLONGED ILEUS**

■ NEUROGENIC	■ METABOLIC	■ PHARMACOLOGIC	■ INFECTIOUS
Spinal cord lesions or injury	Hypokalemia Uremia	Anticholinergics Opiates	Systemic sepsis Pneumonia
Retroperitoneal process hematoma, tumor	Ca ²⁺ , Mg ²⁺ imbalance	Autonomic blockers	Peritonitis
Ureteral colic	Hypothyroidism Diabetic coma or ketoacidosis	Antihistamines Psychotropics Phenothiazines Haloperidol Tricyclic antidepressants Clonidine Vincristine	Herpes zoster Tetanus Bacterial overgrowth (blind loop)

(see earlier). To differentiate early postoperative obstruction from ileus, contrast studies or a CT scan is helpful. The latter may be useful if other abdominal pathology such as an abscess could be contributing to the clinical picture. CT with oral contrast has a sensitivity and specificity of 90% to 100% in distinguishing ileus from a complete postoperative SBO.¹²⁵ However, it is less reliable in distinguishing ileus from a partial SBO.¹²⁵ If the diagnosis is uncertain after CT, upper gastrointestinal contrast studies (enteroclysis) with water-soluble radiopaque contrast material (e.g., Gastrografin) are especially helpful in distinguishing ileus from partial SBO (which more closely mimics ileus than complete SBO) and in identifying the severity of partial obstruction.¹²⁵

6 Management. A normal POI is usually self-limiting. Nevertheless, there are a number of interventions that are effective

in reducing the duration of a normal postlaparotomy ileus (Table 48.9). Midthoracic epidurals with neuraxial local anesthetics have been shown to hasten the return of bowel function compared to systemic or epidural opioids.^{119–121} Midthoracic local anesthetic epidurals block nociceptive afferent signals from the surgical site as well as sympathetic efferent outflow; this is useful for 48 to 72 hours postoperatively.

The goals in management in the normal period of postoperative ileus are to prevent uncomfortable distention, vomiting, and aspiration. Classic studies^{6,10} indicate that flatus and the air accumulating during intestinal distention is derived largely from swallowing. Under normal circumstances, flatus is passed as early as 30 minutes after a “test bolus” of air is administered by tube into the stomach. Thus, passage of flatus is used, in reliable patients, as the index indicating coordination of all segments of the gastrointestinal tract and resolution of ileus.

For many years, the mainstay of therapy was the use of nasogastric suction to prevent accumulation of swallowed air and secreted fluids in an alimentary tract not yet coordinating flow distally. Subsequent studies have demonstrated that the putative benefit does not compensate for risks of aspiration and discomfort of the tube. Thus, in routine abdominal cases such as colectomy, nasogastric tubes are used selectively^{126,127} in patients who are felt to be at risk for complications of ileus, based on the surgeon’s judgments about intraoperative findings or manipulations—prolonged handling and packing of the bowel, anticipation of intensive use of narcotics or other antikinetic agents, presence of sepsis or peritonitis, or extensive blood loss. Otherwise, a nasogastric tube is used for a short postoperative period or never placed, with the expectation that a small percentage of patients will require placement for symptoms.¹²⁷ In these cases, the patient is allowed nothing by mouth or to have sips until there is evidence (by listening for bowel sounds or the patient’s report of “rumbles”) that ileus is likely resolving. Intravenous fluids are necessary until the patient can be advanced to full intake of his or her requirements, usually after flatus is passed.

In addition, correctable conditions such as electrolyte disturbances or uremia are investigated and rectified. Mobilization has other benefits in reducing morbidity.^{128,129} Early feeding is thought to stimulate gastrointestinal hormones, secretions and motility, and coordinated propulsive activity. In addition, early feeding may improve immune function and reduce infectious and catabolic complications.^{97,130} Despite the use of laxatives with prokinetic agents, no controlled trial exists to assess the possible beneficial effects of laxatives on postoperative ileus.⁹⁷

One treatment, gum chewing, has attracted attention as a simple and inexpensive method of accelerating return of bowel

FIGURE 48.14. Plain supine abdominal radiograph of a patient with ileus. Air–fluid levels are present in the small intestine (*thin arrow*). Gas is seen in the colon (*thick arrowhead*). These findings are characteristic of, but not specific for, ileus. Surgical drains in the pelvis and skin staples (*short arrow*).

function. Mastication stimulates the vagal cholinergic pathways that increase gastrointestinal hormone secretion such as gastrin, pancreatic polypeptide, and neurotensin, which affect gastrointestinal motility.^{131,132} Since the initial publication of one small and underpowered study,¹³³ a number of prospective randomized trials have been conducted to test the hypothesis that gum chewing results in earlier passage of flatus and bowel movement in patients undergoing laparoscopic colectomy.^{134,135} No conclusive evidence has been obtained to demonstrate a clear benefit of gum chewing, although subgroup analysis suggests some patients may benefit.¹³⁵ According to one hypothesis, sorbitol and other hexitols, the key gradients of “sugar-free” chewing gums, may also play a role in the earlier recovery of postoperative ileus.¹³⁶ This hypothesis and its putative benefits are intriguing.

Salt and water disturbances in the body also may influence return of bowel function following laparotomy. In one initial study, patients undergoing colectomy received a restricted perioperative fluid resuscitation regimen or a standard, more liberal fluid resuscitation. The “restricted” group had a quicker passage of flatus and moved their bowels earlier, leading in part to shorter hospital stays.¹³⁷ Subsequent studies^{138,139} have not uniformly suggested that recovery from ileus is faster with temperance in fluid resuscitation, or have indicated that there is a

benefit from fluid restriction protocols but have not reported return of gastrointestinal function as an endpoint.¹⁴⁰ However, this benefit, as well as others, may be more clearly observed when fluid therapy is directed by physiologic assessments of volume status, such as esophageal Doppler monitoring of the great vessels and heart chambers.^{141,142}

Experimental evidence of pharmacologic interventions specifically directed at abnormal surges of neurotransmitters or hormones that might prolong ileus has provided a useful insight into the pathophysiology of postoperative ileus. Opioid antagonists, somatostatin analogues, sympatholytics, injection of local anesthetics into mesenteric nerve roots, and nonsteroidal anti-inflammatory agents, such as ketorolac, appear to promote faster recovery to normal myoelectric activity and intestinal transit times.^{106,143,144} In contrast, nonspecific adrenergic receptor blockers such as propranolol have been found to be ineffective.¹⁴⁵ Opioid antagonists such as alvimopan and methylnaltrexone are peripherally acting opioid antagonists and do not cross the blood–brain barrier.¹⁴⁶ In many, but not all, studies, alvimopan has been shown to hasten postoperative gastrointestinal recovery following bowel surgery and abdominal hysterectomy.¹⁴⁶ In one study where an overall benefit was not observed,¹⁴⁷ subgroup analysis showed that there was a benefit in patients who received patient-controlled,

intravenously administered opiate analgesia, suggesting that prolonged ileus may be shortened if opiates are being used regularly to control pain. However, cardiovascular and neoplastic risks with the use of alvimopan have precluded its widespread use, limiting U.S. Food and Drug Administration approval following partial large- or small-bowel resections with primary anastomosis.¹⁴⁶ Additional studies¹⁴⁸ have suggested a benefit in fast-track pathways of care and routine use for accelerating recovery of ileus following laparotomy may be recommended under circumstances in which opiates are used liberally for pain control.

Prokinetic agents such as metoclopramide, cisapride (presently not approved by the U.S. Food and Drug Administration), and erythromycin have been evaluated for their efficacy in shortening the duration of POI. For ileus following upper gastrointestinal procedures (e.g., pancreaticoduodenectomy), such medications may be effective in promoting gastric emptying.¹¹² For general abdominal procedures involving the small intestine, colon, and retroperitoneal structures such as the aorta, there has been limited success in using such agents to shorten recovery times.^{113,114} In multiple controlled studies, metoclopramide did not have significant impact on the duration of ileus.^{114,118} In other studies, no benefit was observed when patients were given erythromycin.^{113,119} Promising results have been observed with cisapride, which significantly reduced the duration of ileus. The results would depend on the route of its administration.^{120–128} However, this medication is no longer approved for use in the United States due to the occurrence of potentially fatal arrhythmias.¹²⁹

Along with pharmacologic measures, it should be emphasized that, in otherwise routine laparotomy or laparoscopy, gentle handling of tissues, meticulous attention to hemostasis, and applications of sound principles of wound management are likely to have the greatest impact on optimizing recovery from ileus and minimizing the incidence of prolonged ileus. Efforts to reduce incision size and time spent handling the intestines through the use of laparoscopic approaches clearly improve recovery from ileus in some, if not all, patients undergoing standardized intra-abdominal procedures such as appendectomy¹⁴⁹ and colectomy.¹⁵⁰ Even in open procedures,¹⁵¹ standardization of management and effective communication help expedite clinical fast-track pathways and facilitate earlier recovery of bowel function and discharge from hospital.^{97,142,148} Currently effective measures to minimize the prolongation of ileus are summarized in Table 48.10.

TABLE 48.10 MANAGEMENT

MEASURES TO PREVENT PROLONGATION OF ILEUS

- Minimization of trauma to tissues; using proper technique in the operating room with gentle handling of bowel during surgery
- Minimal use of narcotics for analgesia, for any route of administration (intravenous, intramuscular, epidural)
- Use of opioid antagonists (alvimopan)
- Generous use of midthoracic epidural anesthesia with local anesthetic use
- Use of nonsteroidal anti-inflammatory (cyclooxygenase-2 inhibitors) agents for analgesia
- Early feeding
- Correction of any electrolyte or metabolic imbalances
- Early recognition of septic complications (e.g., abdominal abscess, pneumonia, central line sepsis) that may contribute to prolongation beyond the expected period for ileus

Colonic Pseudo-obstruction (Ogilvie Syndrome)

Etiologic Factors. Acute pseudo-obstruction of the colon, also known as *Ogilvie syndrome*,¹⁵² is a paralytic ileus of the large bowel, characterized by rapidly progressive abdominal distention, often painless.¹⁵³ Although the distention of the colon is not due to mechanical obstruction, the wall of the bowel, particularly that of the cecum, can become sufficiently distended so that its blood supply is compromised. Gangrene, perforation, peritonitis, and shock can follow. In 95% of the cases, there is an underlying disease.^{153,154}

Major risk factors for development of Ogilvie syndrome include traumatic injury (11%); infections such as pneumonia and sepsis (10%); obstetric/gynecologic conditions (10%); myocardial infarction and congestive heart failure (10%); abdominal and pelvic surgery (9%); neurologic conditions such as Parkinson disease, spinal cord injury, multiple sclerosis, and Alzheimer disease (9%); orthopedic procedures (7%); other medical conditions including metabolic imbalances (e.g., hypokalemia, hypocalcemia, hypomagnesemia) (32%); and other surgical conditions (12%).^{152,154} Evidence suggests that Ogilvie syndrome is thought to be related, at least in part, to sympathetic nervous overactivity or interference with sacral parasympathetic efferents, although there is little direct experimental evidence for this.¹⁵³ It is postulated that the distal colon becomes atonic on interruption of the S2 to S4 parasympathetic nerve fibers.

Diagnosis. This syndrome is commonly encountered in patients hospitalized over 3 to 7 days, often in men older than 60 years of age. Primary manifestations include gastrointestinal symptoms such as nausea, vomiting, abdominal pain, constipation, or even diarrhea with great variability.^{153,154} Labored breathing, caused by abdominal distention, is often part of the clinical picture. Other than distention, there are no characteristic physical or laboratory findings for this syndrome. The abdomen resonates with percussion. Sounds from the small intestine are present and may not be high pitched, as they are in intestinal obstruction.

Laboratory findings associated with this syndrome may include hypokalemia, hypocalcemia, and hypomagnesemia, which are implicated as etiologic factors. Leukocytosis, elevation of the sedimentation rate, or C-reactive protein is also present if inflammation is initiated or perforation is impending.

The diagnosis is usually apparent from plain films. Radiographs of the abdomen may reveal air in the small bowel and distention of discrete segments of the colon (i.e., cecum or transverse colon often up to the splenic flexure) or the entire abdominal colon. Haustral markings disappear with increasing distention. In doubtful cases in which bowel necrosis is not a significant worry, a Hypaque contrast enema can establish the nonmechanical nature of the dilatation. Alternatively, colonoscopy can be diagnostic as well as therapeutic. Features suggesting the complication of bowel ischemia may include localized tenderness, worsening leukocytosis, metabolic acidosis, evidence of sepsis, or a rapidly deteriorating clinical course.

It is important to differentiate this syndrome from toxic megacolon and mechanical obstruction before establishing a final diagnosis. Mechanical obstruction of the colon, occurring in volvulus or obturator obstructions from cancer or diverticular disease, presents with acute pain along with distention. In contrast, pseudo-obstruction is less often associated with acute pain and more likely to present with discomfort due to distention. However, lack of pain in postoperative patients on opiates or elderly patients cannot exclude mechanical obstruction. In plain radiographs, the pathognomonic signs of mechanical obstruction such as lack of gas in the distal colon or rectum and air-fluid levels in the small intestine can also be

TABLE 48.11 MANAGEMENT**TREATMENT FOR PSEUDO-OBSTRUCTION**

TREATMENT	BENEFIT
Nasogastric tube	■ Prevention of swallowed air from passing distally
Neostigmine	■ Increase motility through its parasympathomimetic action ■ Premedication with colonoscopic decompression adding benefits
Erythromycin	■ Increases intestinal motility through motilin receptors in intestinal wall
Colonoscopic decompression	■ Prevention of complications such as perforation
Surgical interventions: total colectomy, Hartmann procedure, percutaneous endoscopic cecostomy	■ Required in case of refractory medical therapy

seen in Ogilvie syndrome. CT scan is currently the standard method for identifying colon pseudo-obstruction and excluding other forms of obstruction.¹⁵³ Patients with toxic megacolon may manifest typically with symptoms such as fever, tachycardia, abdominal tenderness, bloody diarrhea, or other manifestations of chronic inflammatory bowel disease along with evidence of “thumb printing” on an abdomen x-ray film in upright posture. Flexible sigmoidoscopy is contraindicated if toxic megacolon is thought to be likely, but it or contrast enemas¹⁵³ can be useful diagnostically and therapeutically if toxic megacolon is thought unlikely.

Management. Initial management includes resuscitation and correction of any underlying metabolic or electrolyte imbalances (Table 48.11). A physical examination and serial plain abdominal radiographs should be performed to evaluate colonic diameter in order to determine which patients may need colonoscopic decompression or surgery. If the patient is not very uncomfortable and the colonic distention is no greater than 12 cm, conservative treatment can be continued for 1 to 2 days. It may be helpful to place the patient in a prone position or at the knee-chest position with hips held high, alternating right and left lateral decubitus position each hour. A nasogastric tube is helpful if the patient is vomiting and will prevent swallowed air from passing distally. When bowel ischemia is suspected, surgery is indicated. If bowel necrosis is found, the affected segment is resected and an ileostomy or colostomy should be performed. If the bowel is viable, a cecostomy is placed to vent the colon and prevent distention.

If, initially, the distention is painless and the patient shows no signs of toxicity or bowel ischemia, expectant management is successful in about 50% of cases.^{153,155} The risk of spontaneous perforation is approximately 3%, with attendant mortality of 50%. In most patients acute colonic pseudo-obstruction usually resolves within 3 days.^{153,156} If worsening and cecal diameter increases beyond 10 to 12 cm or if it persists for more than 48 hours, intervention is recommended. The duration of distention may be more important than the absolute size of the cecum with respect to spontaneous perforation. Colonoscopy should only be performed by experienced endoscopists. Endoscopic decompression is successful in 60% to 90% of cases, but the condition can recur in up to 40%. This rate of recurrence may be decreased by placement of a decompressive tube. Recur-

rence would require repeated colonoscopic decompression in approximately 40% of cases after initial successful decompression. The placement of a decompression with the aid of a guidewire at the time of colonoscopy may reduce the need for repeated colonoscopic decompression. Rectal tubes are ineffective as primary modalities in managing distention of the proximal colon. Such tubes may be useful in promoting passage of air and feces after colonoscopy but should not be used as a substitute for colonoscopic decompression. Percutaneous endoscopic left-sided colostomy (PEC), a minimally invasive technique, can be used to treat pseudo-obstruction provided these cases are carefully selected in the hands of a skilled endoscopist because of a high failure rate caused by infection.¹⁵⁷

In anecdotal reports, prokinetic agents such as cisapride and erythromycin have been used to treat Ogilvie syndrome with some success. Erythromycin acts by binding to motilin receptors in the small intestine, causing intestinal smooth muscle contraction and perhaps better coordination with colonic motor function. Anecdotal reports have suggested the success of erythromycin treatment on either intravenous route for 3 days or oral route for 10 days.^{158,159} However, the relative paucity of motilin receptors in colon smooth muscle may explain why erythromycin is only anecdotally effective in relieving colonic pseudo-obstruction. Successful resolution of pseudo-obstruction has been reported with sympatholytic agents or spinal sympathetic block. The efficacies of these modalities have not been systematically evaluated.^{153,160}

Neostigmine, a parasympathomimetic, is used in the treatment of acute colonic pseudo-obstruction. The decompression with this drug has been achieved in 80% to 100% with a recurrence rate of 5%.¹⁵³ Neostigmine may be a viable alternative to colonoscopy in pregnant women, provided mechanical obstruction is properly excluded. The administration of a polyethylene glycol electrolyte balanced solution after initial resolution of colonic dilation may reduce the recurrence rate with use of neostigmine.¹⁶¹

Neostigmine has expected cardiovascular side effects such as bradycardia, hypotension, and dizziness and is excreted via the kidneys. The few relative contraindications to its use in treatment of acute colonic pseudo-obstruction are a baseline heart rate of less than 60 beats per minute or systolic blood pressure of less than 90 mm Hg, active bronchospasm requiring medication, a history of colon cancer or partial colonic resection, active gastrointestinal bleeding, pregnancy, or a serum creatinine concentration of greater than 3 mg/dL (265 μ mol/L). Other side effects would include mild to moderate crampy abdominal pain, excessive salivation, and vomiting. Side effects such as increasing airway secretions and bronchospasm can be reduced by concomitant use of glycopyrrolate without reduction of colonic response.^{162,163} Ponc et al.¹⁶⁴ recommend use of neostigmine prior to colonoscopy, based on its easy administration, lower expense, and superior results in comparison to colonoscopy. Reported rates of response to treatment with neostigmine are 91% (single administration) and 100% (second administration) in a group of 21 randomized patients.^{153,164} Colonoscopy is associated with morbidity of 3% and mortality of 1%. Further studies of this combination therapy are warranted. It should be emphasized, however, that patients should undergo immediate exploration if they exhibit signs of clinical deterioration or bowel perforation (peritoneal signs on physical examination or free air on radiographs).

Surgery is reserved for patients not responding to medical and endoscopic management and for patients who develop signs of peritonitis or perforation. Percutaneous endoscopic cecostomy can also be performed if conservative measures fail.¹⁶⁵ Cecostomy tubes are often poorly tolerated because of issues related to skin breakdown; in the authors' opinion, this approach is advisable only when more extensive surgical procedures are considered too risky. Procedures such as total colectomy, ileostomy, and Hartmann procedure are taken into consideration in case of perforation.¹⁵³

CHAPTER 49 ■ CROHN DISEASE*

FABRIZIO MICHELASSI AND SHARON L. STEIN

KEY POINTS

- 1 Crohn disease is a chronic inflammatory disorder of the gastrointestinal tract with varied presentations.
- 2 Although no cure exists for Crohn disease, symptoms can be ameliorated with medical therapy, and surgical intervention is reserved for when medical treatment fails or to treat complications of disease.
- 3 Understanding medical therapies for Crohn disease is imperative for the appropriate perioperative care of patients.
- 4 Indications for surgical intervention in Crohn disease include failure of medical management, obstruction, and septic complications.
- 5 The recurrent nature of Crohn disease requires preservation of bowel length with each surgical intervention to prevent complications of malabsorption and decreased intestinal length.

- 1 Crohn disease is a chronic inflammatory disorder of the gastrointestinal tract that can affect patients from the mouth to the anus. Crohn disease was first described by Dalziel in 1913¹ but derives its name from Burill Crohn, the first author of the
- 2 now classic paper published in 1932.² Although much has been discovered regarding the etiology and treatment of Crohn disease in recent years, there remains no medical or surgical

cure for this disease. Treatment of Crohn disease consists primarily of medical management and modulation of symptoms, with surgical involvement when complications or escalations of symptoms occur. The course and severity of Crohn disease is affected by its location and disease characteristics, and are difficult to generalize. Patterns of disease and involved segments vary from ileocolic disease, the most common surgical manifestation, to colon disease, to pan-intestinal tract disease. Over 70% of patients will require a surgical intervention at some point in their lives and over half of patients will require multiple surgical interventions. A comprehensive understanding of the disease process and surgical options is imperative for appropriate treatment of the disease.

*This chapter has been adapted from the fourth edition of *Greenfield's Surgery* and the authors are grateful for the contributions of previous authors Roger D. Hurst and Alessandro Fichera.

EPIDEMIOLOGY

Current estimates are that 400,000 to 600,000 Americans are affected by Crohn disease and four new patients are diagnosed with Crohn disease annually per 100,000 people in the United States.³ Traditionally, the United States and Europe have a higher prevalence than Asia, South America, or Africa. Patients of Ashkenazi Jewish descent have higher rates than people from other ethnic groups. Within the United States and Europe, there is variation in concentration of cases; Crohn disease is almost twice as prevalent in northern populations.⁴

A familial predilection for Crohn disease exists; one of five patients has a relative with ulcerative colitis or Crohn disease. Additionally, the presence of a first-degree relative with inflammatory bowel disease increases the risk of developing Crohn disease 6- to 10-fold.⁵ No direct mendelian pattern of inheritance has been discovered.

ETIOLOGY OF CROHN DISEASE

The exact etiology of Crohn disease remains unknown. Strong associations between Crohn disease and immunologic, genetic, bacterial, and epidemiologic factors exist and have been the focus of significant research.

Current theory centers on the altered immune response of patients with Crohn disease. Affected patients appear to lack the ability to respond appropriately to periodic bacterial penetration from the gastrointestinal lumen to the circulatory system. The normal immunologic response is to upregulate inflammatory mediators in response to bacterial incursions and downregulate these systems when they are no longer needed. Patients with Crohn disease lack variable regulation and differentiation, resulting in an uncontrolled inflammatory state and chronic changes in the intestinal wall.⁶

Research into the source of this altered inflammatory response has focused on the discovery of genomic changes.⁷ The NOD2 gene, located in the pericentromeric region of chromosome 16, is a gene of particular interest. NOD2 appears to have a role in bacterial sensing and links to the muramyl dipeptide protein present on virtually all bacterial cell walls. Mutations at this locus result in loss of function affecting innate cell response to bacteria and may be partly responsible for the immunologic changes seen in Crohn disease.⁸

Other theories have focused on infectious sources as the etiology of Crohn disease. Associations with specific infectious agents including *Mycobacterium paratuberculosis*, *Helicobacter pylori*, *Escherichia coli*, and various viral agents exist. Bacterial and viral markers have been found in surgical specimens. However, no single bacterial or viral source has been a consistent finding as the etiology of the disease.

Epidemiologic factors of disease variance have led to hypotheses regarding social and dietary sources of Crohn disease. It has been hypothesized that colonization of bacteria secondary to water sources, food preservation, or dietary choices places individuals at increased risk for Crohn disease. These theories are supported by epidemiologic factors; antibiotics successfully treat symptoms, immigrants match the incidence rates of their adopted geographic locale, and dietary modifications improve symptoms. Smokers are at increased risk for contracting Crohn disease, and smoking exacerbates Crohn disease. No specific component within cigarettes has been shown to act as a clear aggravating or inciting factor.⁹

DIAGNOSIS

Diagnosis is based on a combination of clinical history, physical examination, and laboratory, endoscopic, and radiographic findings, but no definitive test for Crohn disease exists. The

FIGURE 49.1. Small-bowel follow-through demonstrating stenosis in the jejunum of a patient with Crohn disease. Dilation is noted upstream of the narrowed segment.

varied location and pathologic features may complicate diagnosis. Approximately 60% of patients have involvement of the ileum, with or without cecal disease. Colonic disease presents in 15% to 20% of patients. Ten percent of patients have proximal small bowel involvement and 15% of patients have multiple sites of disease throughout the gastrointestinal tract.¹⁰ The peak age of diagnosis is between 15 and 25 years of age with a second peak between 55 and 65 years. Crohn disease is uncommon prior to the age of 6 years.

DISEASE PATTERNS

Crohn disease is categorized by three general disease categories: inflammatory disease, stricturing disease, and perforating disease. It is believed that these patterns do not represent distinct disease entities but rather a continuum of the disease. An inflammatory disease pattern is typically characterized by mucosal ulceration and thickening of the bowel wall, resulting in narrowing of the intestinal lumen (Fig. 49.1). Symptoms of the inflammatory pattern of disease are characteristic of chronic obstruction and include weight loss, nausea, abdominal pain, bloating, and change in bowel habits. A stricturing disease pattern is characterized by intestinal luminal narrowing, forming cicatricial strictures surrounded by fibrotic scar tissue. Unlike the inflammatory pattern, stricturing disease is rarely amenable to medical management.

Perforating disease is characterized by the macroscopic or microscopic presence of fistulas and abscesses. Perforating disease typically begins on the mesenteric portion of the intestinal lumen and bores through the bowel wall. Tracks may penetrate for only a short distance and form blind tracks or sinuses, or continue into an adjacent segment of intestine, into an abdominal organ, or through the abdominal wall. Abscesses may cause obstructive symptoms, fevers, abdominal pain, or sepsis. Fistulas are often asymptomatic but, depending on the location, can result in diarrhea, fecaluria, pneumaturia, or enteric drainage through the abdominal wall or the vagina.

CLINICAL PRESENTATION

Patients with Crohn disease most frequently present with abdominal pain. The location of pain varies by disease location, but abdominal pain and anorexia are common regardless of

location. Postprandial crampy abdominal pain and bloating are characteristic of obstructive disease, while septic complications are usually associated with steady pain and localized tenderness. Weight loss and fatigue secondary to anemia are frequent complaints. Right lower quadrant pain mimicking appendicitis is a frequent presentation of ileocolic disease. Patients with Crohn colitis may also present with diarrhea, which may be bloody. Increased fecal urgency and incontinence often coexist with colorectal disease. Delayed gastric emptying may signify gastroduodenal disease. A history of prior appendectomy, irritable bowel syndrome, and food allergies is common. A complete history of patients with Crohn disease includes questioning for secondary symptoms of Crohn disease, such as rashes, mouth ulcers, uveitis, liver abnormalities, and musculoskeletal problems.

Examination of a patient with Crohn disease should assess signs of diffuse or localized peritonitis secondary to perforation, abscess, and toxic megacolon, necessitating prompt surgical intervention. Physical examination should note signs of obstruction, such as abdominal distention and abnormal bowel sounds. Masses and tenderness are frequent findings. Particular attention should be given to prior scars and the presence of abdominal or vaginal drainage, which may signify enterocutaneous or enterovaginal fistulas. Rectal examination should evaluate perianal disease, skin tags, abscesses, fissures, scarring or fistulas, and sphincter tone. An atypical location of perianal disease, such as lateral fissures, or recurrence of perianal disease should raise a suspicion for Crohn disease and warrant further evaluation, even without other intestinal symptoms.

Laboratory testing of patients with Crohn disease may reveal metabolic derangement, acute infection, and malnutrition. Electrolyte disturbances and renal insufficiency are common in patients with severe diarrhea. An elevated white blood cell count, elevated sedimentation rates, and elevated C-reactive protein levels are indicators of acute inflammatory disease or infection. Patients are often anemic, with decreased folate and vitamin B₁₂ levels secondary to ileal disease and malabsorption. Albumin, prealbumin, and transferrin testing can demonstrate evidence of malnutrition secondary to acute or chronic weight loss. Although no definitive laboratory testing exists for Crohn disease, the presence of perinuclear antineutrophil cytoplasmic antibodies (pANCA) and absence of antisaccharomyces cerevisiae antibodies (ASCA) may help differentiate Crohn disease from indeterminate colitis or ulcerative colitis.

EXTRAINTESTINAL DISEASE

Extraintestinal manifestations of Crohn disease occur in up to 25% of patients with Crohn disease and are most likely to occur in patients with ileal disease.¹¹ Patients may present with dermatologic disorders, ocular disease, arthralgias, hepatic dysfunction, and deep venous thrombosis. Some other manifestations, including peripheral arthritis, episcleritis, aphthous ulcers, and erythema nodosum, which generally parallel the activity of the intestinal disease, and symptoms often regress with successful medical or surgical treatment. Surgical intervention is occasionally advocated when these extraintestinal manifestations fail to resolve. Ankylosing spondylitis, uveitis, pyoderma gangrenosum, and primary sclerosing cholangitis do not correlate with bowel disease activity, and their clinical course is not attenuated by surgical resection of intestinal Crohn disease.

ENDOSCOPY

The evaluation of Crohn disease should survey the entire gastrointestinal tract. Endoscopic evaluation includes upper endoscopy for evaluation of gastroduodenal ulcers and colonoscopy

with ileal intubation to investigate colonic and ileal disease. Findings typical of Crohn disease include ulcerations, cobblestoning, and skip lesions. The presence of ileal disease may differentiate Crohn disease from ulcerative colitis, though backwash ileitis (present in ulcerative colitis) may make differentiating the two entities challenging. Rectal sparing or fistulous perianal disease may help differentiate Crohn disease from ulcerative colitis. The presence of aphthous ulcers, cobblestoning, and strictures are highly suggestive of Crohn disease.

SMALL-BOWEL RADIOGRAPHY

Small-bowel follow-through and enteroclysis were traditionally used to evaluate the small bowel between the duodenum and the terminal ileum. In both these studies, oral contrast is ingested and serial radiographic imaging is performed with fluoroscopy or still images. Radiographic findings may be distinctive.¹² Mucosal granularity, ulceration, and blunting of normal intestinal architecture may be seen. Abnormal spacing of bowel loops on enterography is characteristic of mesenteric and bowel wall thickening found in Crohn disease. Fistulas may be demonstrated between loops of bowel; strictures and skip lesions may also be visualized.

COMPUTED TOMOGRAPHY

Computed tomography (CT) allows for identification of extraluminal pathology, unavailable on traditional small-bowel studies. CT can evaluate ureteric obstruction, air within the urinary bladder, inflammatory masses, and abscesses. Information provided by the CT scan is integral for planning percutaneous drainage of abscesses. Recent advancements in the use of CT enterography have increased the sensitivity of CT scan for intraluminal pathology. Using a multidetector CT scanner with oral and intravenous (IV) contrast, CT enterography can evaluate the bowel wall for enhancement and the presence or absence of strictures and fistulas. The sensitivity and specificity of CT enterography still falls behind that of traditional small-bowel follow-through and enteroclysis, but are improving with increasing experience.¹³

CAPSULE ENDOSCOPY

Capsule endoscopy is a recent advancement in gastrointestinal endoscopy. Patients swallow a small capsule, which transmits continuous images to a monitor, which is placed on the patient for the duration of the study. This provides direct imaging of the small bowel between the ligament of Treitz and ileocecal valve, not previously accessible by endoscopy. Patients who undergo capsule endoscopy should first be evaluated for the presence of strictures and chronic obstruction, as cases of retained capsule requiring surgical retrieval have been reported.

PATHOLOGY

Pathologic findings of Crohn disease tend to progress from small aphthous ulcers to full-thickness inflammation and fistulas. Aphthous ulcers are small red spots or depressions in the intestine that represent mucosal ulceration over microscopic lymphoid aggregates and are the earliest manifestation of Crohn disease.¹⁴ As the disease progresses, the ulcers enlarge, forming longitudinal ulcerations on the mesenteric aspect of the bowel wall. Further disease progression leads to a serpiginous network of thin, linear ulcerations surrounding islands of edematous mucosa, producing a classic “cobblestone” appearance. Pseudopolyps, which are actually formed by the paucity of normal surrounding mucosa secondary to severe disease, may be seen in Crohn disease (Fig. 49.2A).

FIGURE 49.2. A: Pseudopolyps and full-thickness ulceration in a patient with Crohn disease of the ileum. B: Fat wrapping or “creeping fat” is seen extending over the serosal surface of the bowel of a stenotic, diseased segment of ileum. Fibrotic changes are noted on the cut surface of ileum, extending to all layers of the bowel wall.

Gross pathologic findings including an inflamed thickened mesentery and enlarged regional lymph nodes are found in the majority of patients with Crohn disease. Fatty tissue develops from the mesentery and extends over the serosal surface of the small bowel, resulting in a phenomenon known as “fat wrapping” or “creeping fat” (Fig. 49.2B). Early in the disease progression the bowel wall is hyperemic and boggy, but as inflammation progresses, fibrotic scarring develops and the bowel becomes thickened and leathery.

The inflammation of Crohn disease eventually extends through all layers of the bowel wall. Mucosal ulcerations progress and penetrate through the bowel wall, resulting in abscesses, fistulas, or sinuses (Fig. 49.3A). Lymphoid aggregates in the submucosa thicken and extend through the muscularis propria (Fig. 49.3B). Well-developed lymphoid aggregates in edematous or fibrotic submucosa or subserosa are virtually diagnostic of Crohn disease. Noncaseating granulomas are found in up to 50% of surgically resected specimens but are rarely seen in specimens obtained endoscopically (Fig. 49.3C). Although granulomas are a valuable diagnostic feature of Crohn disease, their presence is not pathognomonic and they do not imply activity.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of Crohn disease includes a wide variety of abdominal pathologies. Infectious, ischemic, inflammatory, and functional disorders can all mimic Crohn disease.

Differentiating Crohn disease from appendicitis is a common diagnostic dilemma. Young, otherwise healthy patients with right lower quadrant pain, mild leukocytosis, and inflammation on CT are common to both diseases. Careful CT evaluation can be suggestive of disease primarily arising from the appendix, with appendiceal occlusion, versus inflammation arising from the cecum or terminal ileum. Occasionally, the diagnosis of Crohn disease is made intraoperatively, when a

FIGURE 49.3. A: Deep fissure extending through layers of the bowel wall with preservation of surrounding villi and crypts. B: Diffuse lymphoid aggregates characteristic of Crohn disease. C: Noncaseating granulomas are a valuable diagnostic feature of the disease.

normal appendix and inflamed ileum are noted. If the cecum is normal, performing an appendectomy may be appropriate to prevent future diagnostic dilemmas, but the ileum is not typically resected in this acute setting unless obstruction is complete or medical therapy has failed. Should the ileum require immediate resection, ileocecal resection is suggested. Infectious ileal diseases such as *Yersinia*, tuberculosis, and *Salmonella* are uncommon but can present with similar clinical scenarios.

Noninfectious colitis, most commonly ulcerative colitis, can be confused with Crohn colitis. It is believed that ulcerative colitis and Crohn disease may exist on a spectrum of inflammatory bowel disease rather than as distinct disease entities. Crohn disease is typically distinguished from ulcerative colitis by endoscopic, anatomic, and pathologic findings. Endoscopically, ulcerative colitis tends to start at the rectum and progress proximally. Rectal sparing and skip lesions, common in Crohn disease, are unusual in ulcerative colitis. The presence of perianal and small-intestinal disease is common in Crohn disease and rare in ulcerative colitis. Backwash ileitis, a phenomenon associated with an incompetent ileocecal valve, may confuse the diagnosis, but the presence of ulcers, cobblestoning, fistulas, and disease in the proximal ileum are highly suggestive of Crohn disease. Pathologic findings of transmural inflammation or granulomas are characteristic of Crohn disease and rarely found in ulcerative colitis.

Crohn colitis can be mimicked by other colitides, such as infections (*Clostridium difficile*, *Salmonella*, cytomegalovirus) or ischemic colitis, but endoscopic, bacteriologic, or pathologic findings usually differentiate between diseases. Radiation or nonsteroidal anti-inflammatory drug (NSAID)-induced colitis or enteritis may affect the large or small bowel and can be similar in presentation. History and location may help to differentiate between etiologies.

TREATMENT

5 Neither medical nor surgical therapy is curative for Crohn disease. Management of Crohn disease is focused on the relief of symptoms and prevention of recurrence. As patients with Crohn disease often have multiple recurrences and escalation of symptoms, avoidance of surgical resection to preserve bowel length is an important component in treatment. Medical therapy represents first-line treatment for most symptoms of Crohn disease and is based on the severity of symptoms. The understanding of medical treatments for patients with Crohn disease is imperative for the surgeon, as many medications affect postoperative physiology and risks for surgical complications.

MEDICAL MANAGEMENT

The first line of treatment in Crohn disease is symptomatic supportive care. Many patients find that a bland, low-fiber diet may alleviate the symptoms of bloating and abdominal pain. Bowel rest can decrease disease activity, but remission is often transient. Antidiarrheal and antimotility agents, such as diphenoxylate, loperamide, and diluted tincture of opium, are used for chronic diarrhea related to colitis, ileal disease, or prior bowel resection. These medications decrease intestinal cramping and diarrhea by decreasing intestinal motility. In the presence of severe colitis, these medications are contraindicated as they may precipitate toxic megacolon.

Patients with severe malnutrition may benefit from parenteral nutrition. Data extrapolated from the literature on cancer patients suggest that 1 week to 10 days of preoperative total parenteral nutrition may prevent weight loss, improve nitrogen balance, and reduce perioperative complications.¹⁵ The risks of total parenteral nutrition must be weighed carefully against the benefits of nutritional optimization.

Aminosalicylates or 5-aminosalicylic acid (5-ASA) derivatives are commonly used as first-line treatment for patients with mild to moderate Crohn disease of the large and small intestine. These medications inhibit proinflammatory mediators and are designed to deliver medications to a specific bowel segment. Diffusion-dependent medications (Pentasa) target the distal small intestine and are effective in patients with diarrhea. pH-dependent medications (Asacol) are effective in the terminal ileum and ascending colon where the bowel pH reaches 6 to 7. Flora-dependent derivatives (Colazal, sulfasalazine) rely on colonic flora to break the diazobond and work most effectively in the colon.

Aminosalicylates may be taken orally or rectally and have been shown to be effective to prevent relapse after medically induced remission or surgical resection.¹⁶ Patients on ASA derivatives are not at increased risk of postoperative complications and may be started early in the postoperative period to help decrease recurrence rates and maintain remission.¹⁷ It is critical that 5-ASA derivatives not be confused with acetylsalicylic acid (aspirin) or other NSAIDs frequently used in postoperative patients. NSAIDs have the potential to exacerbate disease activity and should be avoided in patients with Crohn disease.¹⁸

Antibiotics have been demonstrated to improve symptoms of Crohn disease. They are used to treat intra-abdominal and perianal infection and abscesses and to obtain and retain remission in inflammatory and fistulizing disease.¹⁹ The mechanism of action is theorized to be due to altering indigenous luminal bacteria and modifying the aerobic and anaerobic bacteria concentrations in the gastrointestinal tract. Fluoroquinolones, metronidazole, and rifaximin are used commonly.

Historically, steroids were the first-line treatment of acute flares of Crohn disease and were used for medically refractory disease. Recent medical literature has de-emphasized the use of steroids in favor of antibiotics and biologic and immunologic pharmacotherapies. Multiple studies have demonstrated that steroids may be helpful in achieving remission, but only about 30% of patients will maintain remission without continued steroids.²⁰ Steroids may be administered orally, intravenously, or rectally.

A limitation of steroids is the extensive side effect profile, which includes osteonecrosis, diabetes, myopathy, infection, and adrenal suppression. Intravenous and oral medications with systemic absorption have a high risk of steroid-induced side effects. Orally available budesonide and topical enemas have decreased systemic absorption and side effects. In general, chronic use of doses of 20 mg/d or higher portends a worse prognosis, with an increased risk of surgical intervention.²¹

The thiopurines azathioprine (AZA) and 6-mercaptopurine (6-MP) are used for treatment of moderate to severe disease and have been particularly useful for patients with fistulizing disease. Studies have shown 6-mercaptopurine and azathioprine to be effective in decreasing recurrence, ameliorating fistulizing disease, and maintaining remission.²² The mechanism of action is induction of apoptosis and inhibition of ribonucleotide synthesis. Side effects of these agents include bone marrow suppression, hepatitis, pancreatitis, and lymphoma, which can be severe and limit usage. Approximately 20% of patients are intolerant to the medications. These medications are not thought to be a major risk factor for patients undergoing surgical intervention.

Methotrexate has been used in patients to facilitate weaning from steroids, particularly in patients intolerant to 6-MP/AZA. Studies in Crohn disease demonstrate an increased rate of remission and ability to wean steroids when compared to placebo.²³ Side effects include bone marrow suppression, pneumonitis, and cirrhosis. Methotrexate is not thought to be a particular risk factor for postoperative complications.

One of the most important recent advances in the medical treatment of Crohn disease is the use of biologic agents. Infliximab

(Remicade) was the first such agent to be introduced. It is a monoclonal antibody directed against tumor necrosis factor- α (TNF- α). While infliximab was initially used only in patients with severe fistulizing disease, its use has been broadened to patients with moderate to severe inflammatory disease, fistulizing disease, and medically refractory disease. Practitioners advocate its use in patients with severe disease as a first-line “top-down” approach. This theory advocates starting patients on traditionally second- or third-line drugs to induce a quicker remission. Studies have demonstrated increased rates of clinical remission and improvement of fistulizing disease.²⁴ Similar agents, including adalimumab (TNF antibody), Visilizumab (CD3 antibody), and certolizumab (TNF), are increasingly available and approved for use in Crohn disease. Significant side effects include rare opportunistic infections and reports of lymphoma. Patients may develop severe anaphylaxis during administration and may form antibodies to these medications. Immunosuppressive therapy is also believed to increase the risk of postoperative infectious complications.

INDICATIONS FOR OPERATION

The indications for surgical intervention in patients with Crohn disease are listed in Table 49.1.

Failure of Medical Management

- 4 Failure of medical management is the most common indication for surgical intervention.²⁵ Failure can occur in a number of ways: patients may continue to worsen, despite maximal medical therapy; medical management can fail to induce remission or quell signs of acute flare; or side effects of medical treatment such as pancreatitis, hepatitis, diabetes, lymphoma, anaphylaxis, and psychosis may limit its use. Alternatively, patients may be unwilling to start or continue medications secondary to the risk of side effects. Each of these reasons may be an indication for surgical intervention.

Intestinal Obstruction

Intestinal obstruction generally occurs secondary to inflammatory or stricturing disease. Partial or complete obstruction is a common indication for surgery in patients with Crohn disease,¹⁰ but acute obstruction is rare. Initial treatment usually involves bowel rest, antibiotics, and supportive therapy. Partial small-bowel obstruction related to acute inflammation can often be managed with medical therapy. Traditionally steroids were used, but recently, new therapies such as infliximab and adalimumab have proven useful in inflammatory disease. Stricturing disease is less likely to respond to medical treat-

ment. Patients with Crohn disease may also have obstruction secondary to adhesions, or volvulus or herniation secondary to prior surgical intervention and should be treated accordingly.

Short-segment strictures may be considered for endoscopic dilation if they are endoscopically accessible in the duodenum, ileum, or colon. Endoscopic dilation has been shown to be safe and efficacious in several studies²⁶ and may be performed with or without simultaneous local treatment with steroid injection.²⁷ If this approach is used, repeated procedures are often necessary.

Failure to resolve, escalation of symptoms, or signs of sepsis are indications for surgical treatment. Most cases of obstruction will eventually require surgical treatment. Obstruction can be treated with resection, strictureplasty, or a combination of the techniques.

Abscess and Inflammatory Masses

Intra-abdominal abscesses and inflammatory masses are frequent indications for surgical intervention. Abscesses result from a localized, contained perforation or fistulization of diseased bowel; small abscesses are often contained in inflammatory masses. Often the reactive serositis will facilitate adhesions to normal bowel wall and form an inflammatory mass to prevent generalized peritonitis and perforation. Abscesses and inflammatory masses may present with an indolent course of low-grade fevers, abdominal pain, and leukocytosis. Abdominal examination may demonstrate a tender mass.

Most abscesses are amenable to antibiotics and drainage. An unstable patient who fails to respond to initial resuscitation and has free perforation or peritonitis should undergo immediate surgical intervention. In a stable patient, a CT scan can evaluate the abscess size, location, and accessibility to percutaneous drainage (Fig. 49.4). Intramesenteric and intraloop abscesses are often inaccessible to drainage. Percutaneous drainage improves clinical symptoms²⁸ and reduces the risk of enterocutaneous fistula.²⁹ However, the source of the abscess is typically severely diseased intestine and most patients will progress to require surgical intervention. Drainage, antibiotics, and parenteral nutrition may reduce inflammation and facilitate a more limited intestinal resection.

Enteric Fistulas

Fistulization is a common manifestation of Crohn disease and results from full-thickness rupture into an adjacent hollow organ or through the abdominal wall. Fistulas may occur at the site of prior anastomoses; ileocolic resection often fistulizes to the duodenum, and colon resections can fistulize to the stomach. Crohn disease may form symptomatic fistulas between proximal and distal loops of bowel or between the small bowel and colon. Enteric fistulas may be found in as many as one third of patients with Crohn disease, but constitute an indication for surgery in only a small minority of patients. Immunologics such as anti-TNF chimeric monoclonal antibody (infliximab) may be used for the medical treatment of fistulous disease.³⁰

Most fistulas between loops of bowel are asymptomatic and are noted incidentally at the time of surgery or on radiographic studies. Up to two thirds of ileosigmoid fistulas are not diagnosed prior to surgery, and the surgeon and patient should be prepared for this possibility.³¹ Occasionally, fistulas may be symptomatic and warrant surgical intervention or escalation of medical therapy. Most commonly this occurs when a large-diameter fistula forms between the ileum and sigmoid secondary to the proximity of these loops of bowel. The large-diameter fistulas may cause shunting of the fecal stream and significant diarrhea. Often, the sigmoid is only secondarily

TABLE 49.1 INDICATIONS

involved and may be separated from the primary loop and repaired primarily; in cases with severe inflammation or primary sigmoid disease, wedge or segmental resection of the sigmoid colon along with ileal resection should be considered.

suture repair. Depending on patient stability, the duration of perforation, and the overall medical condition of the patient, a primary anastomosis, diverted anastomosis, or creation of an end stoma may be indicated.

Urinary and Gynecologic Fistulas

Enterovesical fistulas are encountered in 5% of patients with Crohn disease³² and often in patients with a concomitant ileosigmoid fistula.³³ Patients with this complication present with pneumaturia, fecaluria, and frequent urinary tract infections. An abdominopelvic CT scan may demonstrate air within the bladder, but direct visualization of the fistula is rare. Most surgeons and gastroenterologists agree that patients with urinary fistulas warrant surgery to prevent renal damage from chronic urinary tract infections. Fistulas most frequently track to the dome of the bladder and can be primarily repaired.

Fistulas may occur to the vagina, the fallopian tube, or the uterus. Patients may complain of malodorous, feculent discharge per vagina, causing significant embarrassment and discomfort. Enterovaginal fistulas occur most commonly in patients with prior hysterectomy. Surgical treatment of the fistula is resection of involved intestine and extirpation of the fistulous tract. Associated abscesses should be drained adequately. Enterosalpingeal fistulas are rare and treatment often requires resection of the affected area. Fistulas to the uterus may be treated with bowel resection and débridement of the uterine opening to preserve fertility; in severe cases a hysterectomy may be necessary.

Enterocutaneous Fistulas

Enterocutaneous fistulas occur in approximately 4% of patients with Crohn disease,³² typically from direct penetration of a sinus through the abdominal wall or rupture of a superficial abscess. Prior scars are common sites of drainage. Evaluation of the fistulas with radiographic imaging may demonstrate the existence of an abscess requiring drainage or an obstruction preventing spontaneous healing. The presence of an enterocutaneous fistula does not necessarily dictate the need for surgical intervention; sepsis must be cleared, abscesses drained, and nutritional support supplied if necessary. Enterocutaneous fistulas are often slow to heal, and surgery is ultimately required in many cases. The general principles of management include resection of diseased segment and débridement of the fistulous tract and abdominal wall.

Perforation

Free perforation with peritonitis is a rare complication of Crohn disease, occurring in 1% of patients, and is a clear indication for urgent operation.³⁴ Perforation can occur in the large or small bowel. Resection of the diseased segment is favored over simple

Hemorrhage

Hemorrhage is an uncommon complication of Crohn disease. Massive gastrointestinal hemorrhage occurs more frequently in Crohn colitis than in small-bowel disease. Often, hemorrhage can be managed with endoscopic or interventional therapies and does not require surgical intervention. Hemorrhage in small-bowel disease tends to be more indolent, with episodes of chronic bleeding that require intermittent transfusion.³² Uncontrolled hemorrhage requires localization and resection.

Cancer and Suspected Cancer

Patients with Crohn disease are at increased risk for the development of adenocarcinoma of the colon and small intestine. Current estimates indicate an observed prevalence of 0.3% for small-bowel adenocarcinoma and 1.8% for large-intestinal adenocarcinoma. Small-intestinal carcinoma should be suspected in patients with a sudden change in disease symptoms or acute high-grade obstruction. Nonfunctional bowel excluded from the fecal stream seems to be at particular risk for malignancy. Therefore, bypass surgery should not be performed for Crohn disease of the small bowel. Any stricture treated surgically should be biopsied, if suspicious, prior to performing a stricturoplasty.³⁵ Adenocarcinomas in the setting of Crohn disease tend to be multifocal and poorly differentiated. Segmental resection is appropriate treatment.

Screening colonoscopy with random biopsies should be performed for patients with long-standing colonic Crohn disease. It may be difficult to distinguish neoplastic from inflammatory strictures, and approximately 7% of colonic strictures are malignant. When adenocarcinoma is suspected or histologically proven, surgical treatment is indicated.³⁶ Unlike ulcerative colitis, the recommended treatment for colon cancer in the setting of Crohn disease does not clearly favor total colectomy over segmental resection.

Toxic Colitis

Patients with Crohn disease occasionally develop severe colitis. Severe colitis is defined by Truelove and Witts³⁷ as dilation on radiography (typically defined as transverse colon >5.5 cm in diameter), abdominal tenderness, more than 10 bloody bowel movements per day, fever, tachycardia, anemia, and elevated sedimentation rate. Failure to respond to medical therapy or progression on medical therapy is accepted as an indication for therapy. Subtotal colectomy with ileostomy should be performed.

Growth Retardation

Normal growth is retarded in up to 25% of children affected by Crohn disease. If growth retardation persists despite adequate medical and nutritional therapy, prompt surgical treatment should be carried out before puberty as meaningful growth will not occur after epiphyseal closure. Resection of the affected segment should be performed to enable a decrease of medications and improved physiologic development.

General Principles of Crohn Surgery

Abdominal Exploration. Whether approached laparoscopically or with an open technique, initial evaluation of the entire abdomen should be performed in all patients with Crohn disease. The surgeon should closely examine the small bowel from the ligament of Treitz to the ileocecal valve. Areas of disease, recognizable by dilation and narrowing (chain of lakes), encroachment of mesenteric fat along the serosal surface of the bowel (creeping fat), serosal hyperemia (corkscrew vessels), fistulas, and their exact location from the ligament of Treitz, should be noted. The total length of small bowel should be measured. Bowel downstream to an obstruction must be carefully evaluated for stricture; failure to treat downstream strictures is one cause of early postoperative recurrence.

Resection. Small-bowel resection, specifically ileocolic resection, is the most common surgical procedure performed for Crohn disease. In general, resection should encompass grossly abnormal bowel. Resection of additional bowel to obtain negative microscopic margins has not been shown to decrease the risk of recurrence and microscopically positive margins have not been shown to adversely affect long-term results.³⁸

Division of the mesentery in Crohn disease can be challenging. The mesentery may be massively thickened and traditional transection and ligation techniques may prove inadequate. Often it is difficult to fashion vascular pedicles for simple ligation and attempts to separate mesentery into segments appropriate for clamping may cause inadvertent bleeding. Hematomas in the mesentery further complicate ligation and may cause undermining of the vascular supply to normal intestine. Vessel-sealing devices may be problematic secondary to thickened tissue and provide inadequate hemostasis. Overlapping clamps on either side of the intended line of transection with suture ligation or mattress sutures are a safe method to ensure hemostasis (Fig. 49.5).

A wide variety of anastomotic techniques following bowel resection may be applied. Standard stapling techniques are safe on healthy, pliable bowel, but in the case of severely edematous or hypertrophied intestine, a hand-sewn technique may provide greater versatility. A recent meta-analysis of techniques demonstrated that end-to-end anastomosis is associated with an increased anastomotic leak rate when compared to other anastomotic techniques, and side-to-side anastomosis may provide a decreased anastomotic leak rate, decreased postoperative complication rates, and shorter hospital stay.³⁹ Regardless of the technique employed, the basic premises of a safe anastomosis include ensuring an adequate blood supply, tension-free anastomosis, and waterproof anastomotic seal. Patients with severe malnutrition, anemia, or fecal contamination may not be appropriate for primary anastomosis and a colostomy, diverting stoma, or end ileostomy may be necessary.

Strictureplasty. Intestinal strictureplasty is an alternative approach to resection that preserves bowel length by surgically reconfiguring narrowed segments of bowel to allow passage of enteric contents. The presence of active fistulizing disease, acute inflammation, and phlegmon are contraindications to

FIGURE 49.5. Technique for safe suture ligation and division of thickened and friable mesentery in a patient with Crohn disease. (Adapted from Walsh CJ, Lavery IC. Ileocectomy. In: Michelassi F, Milsom JW, eds. *Operative Strategies in Inflammatory Bowel Disease*. New York: Springer-Verlag; 1999:294–302.)

strictureplasty. Additionally, very long segments of severe, high-grade strictures may not be amenable to current strictureplasty techniques. Most importantly, malignancy in the diseased segment is an absolute contraindication to strictureplasty. Any candidate intestinal segment should be opened and examined for signs of malignancy prior to repair.

The *Heineke-Mikulicz* (Fig. 49.6) and the *Finney* (Fig. 49.7) strictureplasties are both techniques derived from pyloroplasty. The Heineke-Mikulicz is appropriate for diseased segments 7 cm or less in length. A longitudinal incision is made on the antimesenteric border of the bowel and closed in a transverse fashion, increasing the luminal width of the bowel. The Finney strictureplasty can be used for diseased segments up to 15 cm in length. In this technique, the bowel is folded into a U shape, and a longitudinal incision is made between mesenteric and antimesenteric borders. Sutures are placed on the posterior wall of the enterostomy, beginning at the apex, and continued the entire length of the enterostomy. Functionally, the Finney strictureplasty creates a diverticulum on the lateral edge of the bowel, which may cause stagnation of the fecal stream and lead to bacterial overgrowth. The Finney strictureplasty is used less frequently than the Heineke-Mikulicz strictureplasty.

More recently, the side-to-side isoperistaltic strictureplasty (Fig. 49.8) has been used for diseased segments longer than 15 to 20 cm in length. In this technique, the mesentery of the diseased segment is divided at its midpoint and the small bowel is transected. The proximal loop is staggered in respect to the distal loop to allow narrowed segments in one loop to be approximated to dilated segments of the second loop of bowel. A two-layered hand-sewn closure is created in a side-to-side fashion. A multicenter, international study recently demonstrated the efficacy and safety of this technique.⁴⁰

Strictureplasty has been demonstrated to have similar perioperative morbidity and reduction in recurrence rates when compared to conventional resections.⁴¹ The most common postoperative complication after strictureplasty is hemorrhage from diseased newly sewn segments of bowel occurring in up to 9% of cases. In most cases, bleeding stops spontaneously

FIGURE 49.6. Heineke-Mikulicz strictureplasty. This technique is limited to patients with short-segment disease in close proximity. (Adapted from Milsom JW. Strictureplasty and mechanical dilation in strictured Crohn's disease. In: Michelassi F, Milsom JW, eds. *Operative Strategies in Inflammatory Bowel Disease*. New York: Springer-Verlag; 1999:259–267.)

with observation alone. Occasionally, arteriography has been used to infuse localized vasopressin into branches of the superior mesenteric artery. Rarely is surgical intervention required to control postoperative hemorrhage. Sepsis and anastomotic dehiscence occur postoperatively in only 2% of strictureplasties. Several small studies seem to demonstrate reduced recurrence rates, but no randomized controlled trial has compared resection versus strictureplasty. Recent studies suggest normalization of endoscopic and radiographic features in previously diseased segments of bowel following strictureplasty; these findings suggest a possible restitution of function in diseased segments that would have significant implications for preservation of bowel length in patients with Crohn disease.⁴²

Minimally Invasive Surgery. Resections of Crohn disease throughout the large and small intestine can successfully be accomplished laparoscopically. Benefits of laparoscopic surgery include reduced length of ileus and decreased postoperative stay

in several studies.^{43,44} Long-term follow-up has not demonstrated an increased rate of surgical recurrence or intervention in patients who underwent laparoscopic resection. A long-term follow-up series demonstrated that as many as 50% of patients with Crohn disease who had their operation performed laparoscopically were able to undergo a second surgery laparoscopically.⁴⁵ Many patients with Crohn disease are young healthy patients and the cosmetic advantages of a laparoscopic approach can be considerable.

Laparoscopic surgery for Crohn disease may be challenging. Thickened mesentery, abscesses, and fistulas may make dissection difficult. Conversion rates are typically higher in Crohn surgery than other types of laparoscopic bowel surgery, with rates of conversion cited between 4.8% and 29.2%.⁴² It is estimated that surgeons require 10 to 50 cases per year to obtain minimum proficiency, and laparoscopic cases for Crohn disease are recommended only for experienced laparoscopic surgeons.⁴⁶

SPECIFIC SCENARIOS OF CROHN DISEASE

Crohn Disease of the Upper Gastrointestinal Tract

Crohn disease of the duodenum is a relatively rare entity and may be stratified into primary and secondary disease. Primary duodenal involvement occurs in 4% of patients and is generally inflammatory in nature, whereas secondary disease is typically the result of perforating disease from an intestinal segment following prior surgical resection.⁴⁷ Half of all patients with duodenal disease have concomitant disease elsewhere requiring simultaneous surgical intervention.⁴⁸

Primary disease of the duodenum manifests with symptoms due to ulceration and edema, such as heartburn, obstruction, and weight loss. Symptoms can initially be managed with anti-inflammatory and antacid medications, but 90% of patients will eventually require surgical intervention.⁴⁹ The optimal surgical strategy depends on the individual pattern of disease. The Heineke-Mikulicz strictureplasty is best employed for disease involving the proximal duodenum, while a Finney strictureplasty is better suited for disease involving the fourth portion of the duodenum.⁵⁰ If the duodenal stricture is lengthy or rigid and unyielding, an intestinal bypass procedure should be performed. Simple side-to-side retrocolic gastrojejunostomy can be performed for obstructing disease of the duodenum. Improved antiulcer medications such as proton pump inhibitors have minimized the need for simultaneous vagotomy to prevent marginal ulcers. Vagotomy

FIGURE 49.7. Finney strictureplasty. (Adapted from Hurst RD, Michelassi F. Management of small bowel Crohn's disease. *World J Surg* 1998;22:359–363.)

FIGURE 49.8. Side-to-side isoperistaltic stricturoplasty. (Adapted from Michelassi F. Side-to-side isoperistaltic stricturoplasty for multiple Crohn's strictures. *Dis Colon Rectum*. 1996;39:345–349.)

has been associated with the occurrence or worsening of diarrhea in patients with Crohn disease.⁴⁸ Distal duodenal disease may be amenable to Roux-en-Y duodenojejunostomy. Both of these procedures can be performed using either an open or laparoscopic technique with a high rate of success. Surgical resection is generally avoided secondary to a high rate of complications.

Secondary involvement of the second or third portion of the duodenum typically occurs from recurrent disease in the neoterminal ileum after a prior ileocolic anastomosis. Secondary disease of the fourth portion of the duodenum or the stomach usually occurs from primary disease of the transverse colon. Although most fistulas are asymptomatic, shunting of enteric contents may cause malabsorption and diarrhea. Surgical management involves resection of the primary diseased intestine. The duodenum or stomach edges may be débrided to healthy bowel and repaired primarily. In cases of large defect or tension on the repair site, closure with jejunal serosal patch or duodenojejunostomy may be necessary.

Ileal and Small-Intestinal Disease

Ileal and small-bowel disease is common in Crohn disease. As mentioned previously, the bowel should be evaluated for abscesses, fistulas, and strictures. Surgical resection is generally recommended in short-segment disease; stricturoplasty may be preferred in focal circumferential strictures, longer diseased segments, and patients with prior resections to preserve bowel length (Fig. 49.9). Small-bowel disease may be resected using either laparoscopic or open techniques. Adhesions and fistulas may make the laparoscopic approach quite challenging.

The small bowel and ileum are common sites for disease recurrence. Crohn disease is most likely to recur close to the

previously resected intestinal segment. The length of small bowel involved in recurrent disease generally corresponds to the length of bowel originally resected.⁵¹ Diffuse disease, multiple resections, or symptomatic fistulas can lead to malabsorptive syndromes. Most common is the loss of bile salts normally absorbed by the terminal ileum. Bile salts hinder absorption in the colon, leading to increased frequency of stools and frank diarrhea. Bile salt diarrhea is treated with oral cholestyramine, which binds unabsorbed bile acids. More significantly, patients with severe disease may be unable to meet nutritional needs secondary to rapid transit and decreased functional intestinal length, either from disease or resection. These patients may require parental nutritional supplementation on a long- or short-term basis. Fortunately, this occurs only when less than 100 cm of bowel remains. A surgeon should be aware of this issue and attempt to preserve bowel length by minimizing resection and considering stricturoplasty, where appropriate.

Crohn Disease of the Colon and Rectum

Approximately 25% of patients with Crohn disease have isolated colonic involvement, with 5% of these patients with disease isolated to the anorectum.⁵² Careful examination of the anus and rectum is vital, because the procedure of choice for treatment of colonic Crohn disease is determined by extent of involvement and fecal incontinence.

Segmental colitis with rectal and anal sparing occurs in up to 50% of patients with Crohn colitis. Segmental resection has been advocated to spare patients from having a permanent colostomy and maintain absorptive length of the colon. Although patients may have several years of success with segmental resection or ileal rectal anastomosis, colon disease has

FIGURE 49.9. Computed tomography (CT) scan demonstrates a long segment of disease in the terminal ileum. Near-oblivation of the intestinal lumen is demonstrated by minimal passage of contrast. The loop of ileum in the right pelvis is also severely diseased, with mucosal changes apparent on CT scan.

high recurrence rates even in previously grossly normal colon. Long-term recurrence rates are 30% to 70%, and up to 25% of patients eventually require a permanent stoma.^{53,54} The rates of recurrence are similar for total abdominal colectomy with ileoanal anastomosis. Although ileal pouch anal anastomosis is commonly performed in ulcerative colitis, the recurrent nature of Crohn disease renders restorative procedures more risky and therefore this procedure is generally not recommended.

Patients who require emergency colon surgery for toxic megacolon or sepsis should undergo subtotal colectomy with end ileostomy. Subtotal colectomy defers difficult rectal dissection in an acutely ill patient and allows for conversion to an ileorectal anastomosis at a later date. In addition, patients who are acutely ill, malnourished, and immunosuppressed are more likely to develop difficult wound infections and pelvic sepsis from rectal dissection.⁵⁵ Placement of the rectal stump above the fascia prevents intrapelvic or intra-abdominal perforation and should be performed any time the rectal stump appears to carry a high likelihood of dehiscence.⁵⁶

The surgical treatment of Crohn disease of the rectum requires proctectomy with creation of a permanent stoma. Crohn proctitis often occurs with extensive Crohn colitis requiring total proctocolectomy. Care should be taken to preserve pelvic sympathetic and parasympathetic nerves; in benign disease the dissection may be undertaken close to the rectal wall to limit risk of nerve injury. In the absence of significant perianal disease, intersphincteric resection with preservation of the external sphincter decreases the risk of a large perineal wound and adequately removes diseased mucosa of the rectum and anus. If perianal abscesses, complex fistulas, and dense scarring are present, a wide perineal excision is required. In severe cases, the perineal wound may require closure with gracilis or rectus muscle flaps.

Crohn Disease of the Anus

Perianal disease, in the form of abscesses, fistulas, ulcers, strictures, and hypertrophic skin tags, occurs in approximately 30% of patients with Crohn disease, although rarely in isolation. Crohn disease of the anus tends to be recurrent, complex, and progressive in nature.

Fistulas are abnormal connections between the anus or rectum and the perianal skin. Fistulas may be low lying or involve a portion of the internal sphincter muscles. Continence may be severely affected. Fistulas may extend to the vagina or urinary tract. Patients with abscesses should have surgical drainage and treatment with antibiotics including metronidazole and ciprofloxacin. Placement of setons, in the form of suture material or plastic loops, through the fistulous tract can stent the track and prevent formation of abscesses (Fig. 49.10).

Recent advances in medical therapies such as anti-TNF antibody (infliximab) have been shown to be effective in promoting the healing of complex Crohn perianal fistulas. Although short-term data show improvement, longer follow-up shows a low rate of sustained healing, even when combined with surgical drainage of abscesses.⁵⁷ Local injection of immunologics may also be used, especially in the setting of painful skin tags and fissures.

When medical therapy fails to improve symptoms, or in the case of fistulizing disease to the vagina, surgical therapy is advocated. Fistulotomies, or laying open of the fistulous tract, may be used for low-lying fistulas, but the risk of incontinence limits its use in Crohn patients at risk for recurrent fistulas.

FIGURE 49.10. Placement of a seton suture through a transsphincteric fistula-in-ano. (Adapted from Gordon PH, Nivatvongs S, eds. *Principles and Practice of Surgery for the Colon, Rectum, and Anus*. St. Louis, MO: Quality Medical; 1992:221–265.)

Creation of rectal mucosal advancement flaps is appropriate when the rectal mucosa is not grossly affected with Crohn disease. Recent alternative approaches include fibrin-based glue and submucosal xenograft plug, with successful closure in up to 80% of initial studies.⁵⁸ One of the benefits of this technique is the low risk of incontinence or worsening of symptoms after these procedures.

Ultimately, a temporary stoma to divert the fecal stream may be appropriate to facilitate the healing of complex perianal disease such as severe fistulizing disease or rectovaginal fistulas or following creation of a rectal advancement flap. Up to 30% of patients with perianal disease may require permanent or temporary fecal diversion for treatment of their disease. Temporary fecal diversion is sometimes employed in conjunction with rectal advancement flaps to assist in the healing of particularly difficult cases. In severe cases of perianal disease that do not respond to aggressive medical and surgical treatment, fecal diversion typically results in significant relief of local sepsis and inflammation. Unfortunately, disease activity typically recurs rapidly in these cases after reestablishment of the fecal stream.

RECURRENCE

The most common long-term complication following surgery for Crohn disease is recurrent disease. Reported recurrence rates vary greatly. Endoscopic recurrence, which is often asymptomatic, has been reported to vary from 28% to 73% at 1 year and from 77% to 85% at 3 years after ileal resection.⁵⁹ Symptomatic recurrence occurs in 60% of patients at 5 years and 75% to 95% of patients at 20 years. Reports vary, but the rate of reoperation to treat recurrent disease is approximately 20% at 5 years, 33% at 10 years, and 50% at 20 years.⁶⁰

Research has focused on the prevention of recurrence. Some evidence indicates that the use of NSAIDs or nicotine both promote recurrence of disease. All patients with Crohn disease should be strongly advised to refrain from smoking cigarettes or taking NSAIDs.

Patients are often placed on maintenance therapy within days or weeks of surgery. The most common maintenance therapies recommended are controlled-release 5-ASA (Pentasa) and 6-MP, but newer regimens include the use of metronidazole and infliximab. The degree to which postsurgical maintenance therapy lessens the risk for recurrent disease is in some cases only marginal. The effects on long-term quality of life and the cost-effectiveness of postoperative maintenance therapy have not been fully determined. Thus, the decision to recommend maintenance therapy must be individualized for each patient.

CHAPTER 50 ■ SMALL-INTESTINAL NEOPLASMS

DOUGLAS J. TURNER, AJAY JAIN, AND BARBARA L. BASS

KEY POINTS

- 1 Although the small bowel accounts for 75% of the length and 90% of the mucosal surface of the gastrointestinal tract, it is the site of only 1% to 3% of gastrointestinal malignancies.
- 2 As in the colon, small-bowel adenomas may be histologically classified as tubular, tubulovillous, or villous. Adenomas occur predominantly in the duodenum with the majority found in the periampullary region.
- 3 Like adenomas, adenocarcinomas have a predilection for the duodenum, with a marked decrease in frequency moving axially along the small bowel. Approximately 80% of tumors are located in the duodenum or proximal jejunum.
- 4 The gastrointestinal tract is the site of 4% to 20% of all non-Hodgkin lymphomas, being the most common extra-nodal site. The stomach harbors the most lymphomas, followed by the small bowel and then the colon.
- 5 Carcinoids are indolent malignant neuroendocrine tumors that arise from the enterochromaffin cells at the base of the crypts of Lieberkühn.
- 6 Gastrointestinal stromal tumors are characterized by expression of c-kit and PDGFR α gene mutations. While surgical resection is the only curative treatment, adjuvant therapy with imatinib and other tyrosine kinase antagonists can decrease the risk of relapse in patients after resection of high-risk tumors.

1 Small-bowel tumors, both benign and malignant, are uncommon. Although the small bowel accounts for 75% of the length and 90% of the mucosal surface of the gastrointestinal tract, less than 5% of primary gastrointestinal malignancies arise from the small intestine.¹ Although they are unusual, benign small-bowel lesions have been incidentally discovered in 0.2% to 0.3% of autopsy specimens, 15 times more than the number discovered in surgical specimens, attesting to the frequently asymptomatic nature of these neoplasms.² Recent data have reported an increase in the incidence of small-intestinal tumors, a factor at least partly due to improved imaging modalities and to an increasing number of immunocompromised patients.^{1,3} Small-intestinal tumors may originate from cells of epithelial origin (adenomas, adenocarcinomas, or carcinoids), lymphatic tissues (lymphomas), or mesenchymal or neural elements (gastrointestinal stromal tumors, leiomyomas, lipomas, hemangiomas, neuromas, and a wide variety of sarcomas). From 1975 to 2000, the rates increased by almost 50%. This trend reflected increases for adenocarcinomas, malignant carcinoid tumors, and lymphomas in men, and for carcinoid tumors and lymphomas in women.⁴ The small intestine is also a rare site for metastasis from other primary tumors.

EPIDEMIOLOGY

While the relative incidence rates of small-bowel tumors in the United States appear to be increasing,³ there are clearly geographic variations in incidence worldwide. Carcinoid tumors are virtually nonexistent in Asian populations, yet represent about 30% of malignant small-bowel neoplasms in Western series.^{3,5,6} The proportion of benign small-bowel tumors varies from 14% to 52% in various international series, a disparity likely explained by failure to detect the typically asymptomatic benign lesions. Reported rates of non-Hodgkin lymphoma of the small bowel vary from 27% to 72%, a discrepancy due in part to inconsistent categorization of lymphomas as primary or metastatic tumors, but also due partly to geographic variation. Given the rarity of small-bowel tumors and the wide variety of histologies, there are no large case series for any specific histologic subtype in the world literature, making comparisons difficult and definitive incidence rates difficult to confirm.⁷

Although generalizations regarding these rare tumors can be difficult to formulate, certain patterns can be discerned. Small-bowel neoplasms are less common in women than in men: a

male preponderance (3:2 ratio) is reported for both benign and malignant neoplasms. Most patients with small-bowel neoplasms present in their sixth to seventh decade of life. Except for adenocarcinoma, which has a predilection for the duodenum, malignant small-bowel tumors are more common in the distal small bowel. Approximately 20% of tumors arise in the duodenum, 30% in the jejunum, and 50% in the ileum.⁸

PATHOGENESIS

Several hypotheses have been proposed to explain the low incidence of small-bowel tumors, particularly those derived from cells of the intestinal epithelium. These hypotheses postulate that small-bowel neoplasms may arise from disruption of normal small-bowel flora, pH, transit times, or mucosal integrity. Although none of these hypotheses have been verified, they are plausible given what is known about the pathogenesis of other gastrointestinal tumors. The dilute alkaline liquid contents of healthy small bowel are potentially less capable of inducing direct mechanical mucosal injury and disruption than the more solid contents of the colon. The luminal content of the healthy small-bowel lumen does not harbor pathogenic bacteria and their potentially toxic metabolites are not present to induce the genetic alterations implicated in colon carcinogenesis. Rapid transit time through the small-bowel lumen, normally 30 minutes to 2 hours, may limit mucosal exposure to potential carcinogens, whereas the presence of the enzyme benzopyrene hydroxylase in the brush border of the small intestine may provide protection against mucosal damage by detoxifying the carcinogen benzopyrene. The greater concentration and distribution of lymphoid tissue in the intestinal epithelium and submucosa and high levels of luminal immunoglobulin A may provide an immunologic protective mechanism against neoplasia. Some investigators suggest that the high rate of metachronous primary malignancies, observed in up to 20% of patients, and the frequency of multicentric small-bowel malignancies support an alteration in host defenses or a breakdown in this immunologic protective mechanism as an important etiologic factor.

CONDITIONS ASSOCIATED WITH INCREASED RISK FOR SMALL-BOWEL TUMORS

Although the small bowel develops few tumors, risk factors for the development of malignant lesions have been identified. As shown in Table 50.1, several conditions carry an increased risk of neoplasia.

Crohn Disease

Crohn disease is associated with up to a 10- to 12-fold increased risk of developing small-bowel adenocarcinoma,⁹ with carcinoma developing in diseased segments of the bowel with preexisting dysplasia. Three quarters of these small-intestinal cancers arise in the ileum, the area most commonly involved with Crohn disease but the segment of small bowel least commonly affected by adenocarcinoma in healthy individuals. The remaining small-intestinal tumors in patients with Crohn disease are found in the duodenum and the jejunum, following the usual distribution of sporadic carcinoma, which tends to develop in the duodenum. Crohn-associated carcinomas carry a particularly poor prognosis because the tumors are frequently diagnosed at an advanced stage, likely because the abdominal symptoms of the tumor are initially attributed to the underlying inflammatory bowel disease.¹⁰

TABLE 50.1 ETIOLOGY

CONDITIONS ASSOCIATED WITH AN INCREASED RISK OF NEOPLASIA

■ PREEXISTING CONDITION	■ POTENTIAL MALIGNANCY
Adenomatous polyps	Adenocarcinoma
Familial adenomatous polyposis	Adenocarcinoma
Peutz-Jeghers syndrome/hamartomatous polyps	Adenocarcinoma
Leiomyomas	Possible leiomyosarcoma
Neurofibromatosis	Leiomyosarcoma, carcinoid, adenocarcinoma
Crohn disease	Adenocarcinoma
Celiac sprue	Lymphoma, adenocarcinoma
Immunosuppression	Lymphoma
Human immunodeficiency virus infection	Lymphoma, Kaposi sarcoma
<i>Helicobacter pylori</i> infection	Low-grade lymphoma (mucosal-associated lymphoid tissue)
Epstein-Barr virus infection	Lymphoma

Familial Adenomatous Polyposis

Also at risk for the development of adenocarcinoma, primarily of the duodenum, are patients with familial adenomatous polyposis (FAP).¹¹ Close to 100% of FAP patients will eventually develop adenomatous polyps in the duodenum, and the risk of duodenal carcinoma in these patients has been estimated to be 300-fold over that of the healthy population.¹¹ Duodenal and periampullary adenocarcinomas are the leading cause of cancer death in FAP patients who have previously had a colectomy. Careful screening with periodic esophagogastroduodenoscopy and prompt local resection of adenomas is of paramount importance in this patient population. Endoscopic polypectomy is appropriate for small or pedunculated lesions, whereas larger villous tumors, which have a greater risk for adenocarcinoma, particularly in the periampullary region, may require pancreaticoduodenectomy for adequate treatment.

Other Conditions with Increased Risk for Small-bowel Malignancy

Celiac sprue is associated with lymphoma, and to a lesser degree adenocarcinoma, occurring in up to 14% of patients.¹² It is impossible to determine whether patients with celiac disease will develop cancer, but about 8% to 10% of patients with severe small-bowel mucosa biopsy changes develop lymphoma, and this figure has remained remarkably constant.¹³⁻¹⁵ Patients who are diagnosed with celiac disease late in life tend to have a higher incidence of lymphoma than patients who are diagnosed early on. Some have suggested that this discrepancy may be attributed to initiation of a protective gluten-free diet at a much younger age.¹⁵ It remains unclear, however, whether a gluten-free diet decreases the risk of gastrointestinal lymphoma. Dietary compliance did not show a decreased risk of malignancy in a recent study.¹⁶

The neurofibromas of von Recklinghausen disease may undergo malignant transformation, as may leiomyomas of the

small bowel. In Peutz-Jeghers syndrome, hamartomas develop throughout the gastrointestinal tract and may carry a risk of malignant transformation to adenocarcinoma.¹⁷ Whether these malignancies, especially in the duodenum, actually arise from preexisting hamartomas has been poorly documented. Sporadic benign adenomatous polyps are at risk for malignant transformation and should be removed when identified.

Bile acids and their metabolites may have a possible role in the pathogenesis of small-bowel adenocarcinoma. In one study of all patients with small-intestinal malignancy, 12% had a history of cholecystectomy, and of those with duodenal adenocarcinoma, 25% had prior cholecystectomy, although a causative relationship between cholecystectomy and small-intestinal adenocarcinoma remains unproven. Within the duodenum, the periampullary region is the most frequent site of primary carcinoma, although a link between this finding and pancreaticobiliary secretions is unexplored.

Immunosuppression, both iatrogenic following organ transplantation or secondary to disease, places a patient at increased risk for small-bowel malignancy, primarily lymphoma and sarcoma. After solid organ transplantation, patients maintained on immunosuppressive regimens have an incidence rate 45 to 100 times higher than that of nontransplanted persons for non-Hodgkin lymphoma (NHL), a condition termed *posttransplant lymphoproliferative disorder* (PTLD).¹⁸ PTLD accounts for 30% of all malignancies in cyclosporine-treated patients but accounts for only 12% of malignancies in patients without cyclosporine in their regimen. PTLD tends to develop rapidly, often within 12 months of transplantation in cyclosporine-treated patients. The level of immunosuppression appears to influence the incidence of PTLD; patients who require high degrees of immunosuppression to sustain their graft, such as patients with small-bowel, heart, liver, or lung transplants, show rates of lymphoma as high as 30%. In contrast, only 5% of kidney transplant recipients (who generally require less immunosuppression) develop lymphoproliferative tumors. Reduction of immunosuppression remains the mainstay of treatment of PTLD. This can be challenging since reduction of immunosuppression increases the risk of allograft rejection. Additional treatment options include systemic chemotherapy or rituximab.¹⁹ For localized disease, there may also be a role for surgical resection and/or radiation.²⁰ Human immunodeficiency virus (HIV) infection (another form of immunosuppression) is also associated with lymphoma. Lymphoma is the second most common malignancy, after Kaposi sarcoma, in these patients. As life expectancy for patients with HIV infection has lengthened with improved antiviral medications, the rates of lymphoma have increased such that the risk at 3 years now approaches 30%. Two thirds of these lymphomas are extranodal and the gastrointestinal tract is involved in 10% to 25% of cases.

CLINICAL PRESENTATION

There are no pathognomonic signs or symptoms of small-bowel tumors. Complaints, if reported, are nonspecific. As shown in Table 50.2, the most common symptoms—abdominal pain, weight loss, anemia, nausea, and vomiting—do not suggest specific localization and are usually present in about 45% of patients. These vague complaints often lead to diagnostic delay before the correct diagnosis of small-bowel neoplasm is established. Tumor location may influence the time required for detection. Smaller lesions often present earlier in the ileum, where the lumen is narrower and obstruction more likely to develop. As tumors enlarge, symptoms are more likely to develop. Of all lesions measuring at least 4 cm, 75% will cause symptoms, whereas 92% of malignant lesions of that size will be symptomatic. Overall, malignant lesions tend to be more symptomatic than benign lesions, eliciting complaints of abdominal pain and weight loss. In contrast, benign tumors more often present with acute hemorrhage as the primary

TABLE 50.2

DIAGNOSIS

CLINICAL PRESENTATION OF PRIMARY SMALL-BOWEL TUMORS

SIGNS AND SYMPTOMS	FREQUENCY (%)
Benign Neoplasms	
Asymptomatic	47–60
Abdominal pain	24–50
Acute gastrointestinal hemorrhage	29–44
Anemia	28–58
Intermittent obstruction	12–28
Malignant Neoplasms	
Asymptomatic	6–12
Abdominal pain	62–83
Weight loss	38–55
Nausea/vomiting	23–64
Acute gastrointestinal hemorrhage	6–31
Anemia	12–38
Abdominal mass	5–32

symptom or are identified as an incidental finding on a radiologic examination or at laparotomy.

Because of their ill-defined symptoms, both benign and malignant small-bowel tumors frequently present late in their course. Tumors are often diagnosed at the time of emergency surgical exploration for intestinal obstruction, perforation, or massive gastrointestinal hemorrhage. Only in hindsight may a history of abdominal complaints be elicited.

DIAGNOSIS

Diagnosis of a small-bowel neoplasm can be challenging. In most series, the average duration of symptoms prior to diagnosis ranges from weeks to many months. Diagnosis is hindered by the infrequency of these tumors and failure to consider small-bowel neoplasm in the differential diagnosis for patients with nonspecific abdominal complaints. More importantly, diagnosis is delayed because imaging modalities available to study the small bowel are limited. Accurate preoperative diagnosis is rarely established prior to surgery.¹

Plain abdominal radiography is rarely helpful unless the patient presents with obstructive symptoms. For patients being evaluated for gastrointestinal complaints or gastrointestinal bleeding, the diagnosis of small-bowel tumor is usually considered after negative endoscopic evaluation of the foregut and colon. The diagnostic workup should then proceed to computed tomography (CT) scan of the abdomen. In addition to readily identifying bulky mass lesions, imaging allows detection of subtle findings that are highly suggestive of small-bowel tumors. Neoplastic disease must be strongly suspected if the small bowel wall is thicker than 1.5 cm or if there are discrete mesenteric lymph nodes or masses greater than 1.5 cm in diameter. The CT scan may reveal a transition zone, demarcating dilated proximal bowel from decompressed distal bowel. If associated with bowel wall thickening, a tumor is likely, except in patients with clinical characteristics more typical of Crohn disease or those who carry a known diagnosis of Crohn disease.

Tumors of the distal small bowel may show CT findings of ileocolic or jejunoileal intussusception. Diagnosis of intussusception in adult patients warrants operative intervention without further delay. During intussusception, the small-bowel tumor serves as the lead point to pull the small bowel into the

distal small bowel or colonic lumen; the mass lesion precludes spontaneous reduction. In adults, radiographic attempts to reduce an intussusception should not be attempted. Rather, prompt surgical exploration and resection of the nonreduced intussuscepted bowel segment with mesenteric resection should be completed.

If abdominal CT imaging fails to reveal evidence of a small-bowel tumor, one should proceed to the next steps in the diagnostic algorithm for small-bowel lesions, which have changed in recent years due to the greater availability of two new technologies to visualize and assess the small-bowel lumen: interventional methods in endoscopy, endoscopic ultrasound, and now video capsule endoscopy (VCE) and double-balloon enteroscopy (DBE). Prior to the development of these technologies, luminal contrast studies were the next diagnostic step, and there is a place for these studies where expertise in newer technologies remains unavailable. Luminal radiographic follow-through (UGI and SBFT) remain useful to identify areas of partial obstruction and to identify patients in whom VCE may be contraindicated due to the presence of strictures that would prevent passage of the capsule. However, interpretation of subtle findings on UGI and SBFT for the evaluation of possible small-bowel tumors remains challenging, and diagnostic accuracy is only 60% to 70% in most series.

Endoscopic examination of the duodenum is readily accomplished and the diagnostic procedure of choice. Endoscopy also offers optimal means for tissue diagnosis with forceps biopsy, snare polypectomy, or fine-needle aspiration. Endoscopic ultrasound has expanded the diagnostic and therapeutic assessment of mucosal and mural lesions of the small bowel, and is widely utilized to provide structural characteristics of lesions of the duodenum. Accurate staging of depth of mucosal-based lesions is enhanced and identification of submucosal extension can confirm malignancy and dictate a resectional therapeutic approach as opposed to a luminal submucosal excision. Lesions confined to the mucosa but too large for snare polypectomy may be removed with endoscopic techniques and devices that allow endoscopic mucosal resection (EMR), offering both diagnostic and therapeutic efficacy.

Given these poor detection rates, some radiologists support enteroclysis as the primary study of choice for imaging the small bowel distal to the ligament of Treitz. Enteroclysis is a dynamic contrast technique that uses a combination of barium and methylcellulose infused into the small bowel via a nasoduodenal tube to uniformly distend the small bowel without abolishing peristalsis. Expertise in this procedure is important for success and is rapidly losing favor as a diagnostic test given the newer technologies of VCE and DBE. It can be a useful study, however, as in one series, enteroclysis identified 90% of cases compared to 33% by SBFT in the same cohort of patients.

In addition to these techniques that attempt to visualize intraluminal pathology, other modalities are useful in specific situations. Selective visceral angiography may be helpful in the diagnosis of patients with acute or chronic gastrointestinal hemorrhage. Massive hemorrhage is most common with benign smooth muscle tumors and arteriography may provide both diagnostic and temporizing therapeutic advantages if selective embolization of a bleeding vessel can be achieved. Benign vascular lesions, including hemangioma, are more likely to present with occult gastrointestinal blood loss.

Small-bowel Enteroscopy

Endoscopic modalities include push enteroscopy, intraoperative enteroscopy, VCE, and DBE. The older modality of Sonde pull-through enteroscopy is no longer in clinical use. "Push" enteroscopy utilizes a pediatric colonoscope for direct examination of the mucosa of the proximal small bowel.²¹ Biopsy of identified lesions can be performed with this instrument,

although the examination is limited to visualization of only the proximal 2 to 3 feet of small bowel. Performed in the endoscopy suite with intravenous sedation, the procedure is not well tolerated by all patients.

Intraoperative enteroscopy—a combined procedure including an endoscopist who navigates the enteroscope through the lumen on the bowel, which is facilitated by manipulation of the bowel by a surgeon, using laparoscopic, hand-assist, or open approaches—allows full visualization of the small-bowel mucosal surface and the opportunity to surgically treat identified lesions.

VCE with a wireless video capsule endoscope is being employed increasingly in the diagnosis of small-bowel tumors with negative CT scan and upper endoscopy. The device is an ingestible 11 × 26-mm capsule that the patient swallows; it contains a miniature video camera, light source, battery, and transmitter that sends images (up to 60,000 overall) to a recording device worn by the patient.^{22,23} The patient simply swallows the capsule and subsequently passes the device; no sedation is required. VCE is a good test to identify potential small-bowel lesions; however, it does not have the capacity for biopsies, nor can precise localizations along the bowel be determined. Relative contraindications to VCE include obstructive symptoms, motility disorders, and pacemakers. The major complication is capsule retention, which can occur at a stricture; the incidence of this in healthy patients is close to 0%; however, it can be as high as 10% to 25% in patients with small-bowel tumors.²² A dissolvable test capsule is in development to identify those patients in whom the capsule is most likely to be retained. While retention of the capsule may not be considered a complication in those patients requiring surgery for an identified obstructing tumor, it is a much more serious complication in patients who would otherwise be managed conservatively, such as those with Crohn disease (where retention rates have been reported at 5% to 13%).²² VCE has been useful in the identification of all mucosal-based lesions, including neoplasms, of the small bowel. The diagnostic rates are lower with submucosal lesions such as gastrointestinal stromal tumors. The major limitation of VCE is that it can only roughly identify the location of the lesion within the length of the small bowel and it does not offer any therapeutic impact or ability to sample tissue.

DBE is an endoscopic procedure that utilizes a therapeutic endoscope coupled to a pair of inflatable balloons. Sequential inflation and deflation of the balloons allows the endoscope to be pulled through the lumen of the small bowel. The entire mucosal surface can be visualized in antegrade (per oral) or retrograde (per anus) fashion. The procedure requires deep sedation or general anesthesia and considerable technical expertise and experience for successful execution. The major advantage of the procedure over the less complex and safer procedure of VCE is that tissue diagnosis and therapeutic capacity exists with DBE. In a large registry study from Japan, of 1,045 patients undergoing DBE, 144 (14%) were found to have small-bowel tumors. Biopsy confirmed the diagnosis of tumor type in 85 patients including gastrointestinal stromal tumors, lymphoma, and carcinoid tumors. In 45 patients interventional procedures were completed including endoscopic mucosal resection, clipping or coagulation for bleeding, and stent placement. Complications occurred in 3% of patients, including perforation requiring subsequent surgical management.

Despite these multiple diagnostic modalities, more than half of patients with small-bowel neoplasms present with a surgical emergency, and more than half of patients with malignant disease have metastatic spread at the time of operation.

SURGICAL MANAGEMENT

Surgical approaches have changed as laparoscopic procedures for abdominal conditions have been disseminated throughout the surgical community. Laparoscopic approaches are suitable

for isolated benign and nonbulky tumors. Hand-assist ports facilitate these procedures using tactile palpation to identify smaller lesions, particularly in obese patients where the tumors may not be readily identified. Abdominal wall seeding has not been described, although most advocate removal of the tumor in a specimen retrieval bag to avoid tissue contact.

Mesenteric resection is important in tumors characterized by lymphatic spread including adenocarcinoma, carcinoid, and lymphoma. Open procedures, to ensure adequate wide mesenteric resection, may be more appropriate for these tumors. During the surgical procedure, it is essential to carefully examine the entire small bowel, because multiple lesions occur in up to 20% of patients depending on tumor type. Assessment for metastatic disease elsewhere in the abdomen including the liver is also essential.

BENIGN TUMORS OF THE SMALL INTESTINE

Accounting for 30% to 50% of primary neoplasms of the small bowel, benign tumors are poorly characterized. Half the patients with benign tumors are symptom free, even in retrospect, until the need for emergency surgery. Up to 60% of benign small-bowel tumors will be diagnosed at the time of presentation with a surgical emergency including obstruction, massive gastrointestinal hemorrhage, or perforation. For patients who do present with symptoms necessitating evaluation, vague abdominal pain and recurrent gastrointestinal bleeding are the most common. In one series,² 29% of patients with benign lesions presented with an acute hemorrhage and 40% in another series,⁸ a feature that may help differentiate benign from malignant lesions, the latter of which bleed less often. Many more lesions are never identified because they elicit no symptoms.

As noted previously, the diagnostic workup is challenging. In patients with symptoms, investigations should proceed as outlined previously. The sequelae of the neoplasms (obstruction, hemorrhage, perforation) will dictate the pathway of evaluation.

Regardless of the location, the treatment of benign small-bowel tumors is local excision or limited resection. As gross appearance in the operating room may not definitively establish a small-bowel tumor as benign, segmental resection is often the most appropriate surgical approach. Endoscopic resection or submucosal excision via operative enterotomy may be appropriate for small lesions with obvious benign-appearing features such as a lipoma or for multiple symptomatic lesions as occurs with Peutz-Jeghers syndrome²⁴; however, segmental limited resection is usually the most appropriate intervention. Intraoperative examination of the small bowel with careful palpation, including the possible use of intraoperative enteroscopy for evaluation of suspected abnormalities, is essential to rule out synchronous lesions.

ADENOMAS

Unique to the duodenum, Brunner gland adenomas are rare tumors of the proximal duodenum.²⁵ Brunner glands are normally found in the duodenal submucosa and secrete an alkaline bicarbonate-rich fluid and mucus that aids in the neutralization of gastric acid. The pathogenesis of the glandular hyperplasia that is linked to adenoma formation remains unknown. Brunner gland adenomas appear to have minimal, if any, malignant potential. Once identified, local resection via endoscopic means or duodenotomy with submucosal excision should be performed to prevent intussusception or biliary obstruction as the adenoma grows.

As in the colon, small-bowel adenomas may be histologically classified as tubular, tubulovillous, or villous. Adenomas

occur predominantly in the duodenum with the majority found in the periampullary region, but they may also be found in the proximal jejunum. Because roughly 25% of these villous and tubulovillous adenomas harbor malignancy, it is important to identify and resect these tumors when they are identified.²⁶ Submucosal resection (SMR) via DBE has been described for these smaller lesions. It is the preferred approach when technical expertise with these modalities is available. All adenomas are associated with potential risk for malignant transformation, a risk that presumably increases with size, although relative risks of transformation are difficult to determine given the low number of reported cases. Nonetheless, adenomas larger than 2 cm should be considered worrisome for malignancy.

Approximately one third of adenomas in the duodenum present with obstructive jaundice or small-bowel obstruction, leading to ultrasound and abdominal radiography as the initial diagnostic studies. Without these physical signs to direct the workup, appropriate initial diagnostic studies of the duodenum include double-contrast upper gastrointestinal series or esophagogastroduodenoscopy, both of which are equally sensitive in most series. Adenomas appear usually as small intraluminal filling defects and are frequently pedunculated on a stalk (Fig. 50.1). For those few patients subjected to contrast series prior to esophagogastroduodenoscopy, the pathognomonic finding for villous adenoma is a “soap bubble” or “paint brush” sign, in which rounded radiolucent areas are intermixed with a meshwork of contrast material. Esophagogastroduodenoscopy should follow a positive upper gastrointestinal study incorporating endoscopic ultrasound to detect depth of the lesion, potential for invasive disease, and lymphadenopathy. Treatment requires either endoscopic excision or surgical resection for larger invasive lesions. The surgical choices include transduodenal local excision for small lesions, pancreas-sparing duodenectomy for lesions confined to the mucosa, or pylorus-preserving pancreaticoduodenectomy

FIGURE 50.1. A 64-year-old woman with a polypoid lesion in the second portion of her duodenum on upper gastrointestinal series, found to be a benign adenoma at operation.

for larger lesions or periampullary tumors. Duodenal villous tumors demonstrate local recurrence rates of 40% at 10 years, 25% of which are malignant. Based on these retrospective data, pancreaticoduodenectomy is recommended as an appropriate surgical option for benign lesions in selected patients. As mentioned previously, patients with FAP are at particularly high risk for developing duodenal polyps with potential for malignant transformation. After the colon, the duodenum is the second most common site of polyp formation in FAP, and duodenal cancer is the second most common cancer after colon cancer in FAP patients. FAP patients have a 100- to 300-fold greater risk of developing duodenal cancer than the general population.²⁷ Because of this high risk of local recurrence, those patients in whom local excision is performed require annual surveillance with endoscopy.²⁸ In FAP patients with multiple polyps that cannot be completely excised or in patients with dysplastic changes, pancreaticoduodenectomy should be offered.²⁷

LIPOMAS

Lipomas are true fatty neoplasms of the small bowel that are typically asymptomatic. These tumors are most often found incidentally on abdominal CT scans completed for evaluation of other clinical conditions. Lipomas are identified as well-circumscribed lesions of fat density on CT imaging. Unless associated with bleeding or obstruction, small tumors under 2 cm can be safely observed, while larger lesions or growing lesions should be resected to rule out malignant liposarcoma. Because these tumors are polypoid, compressible intraluminal lesions, they are predisposed to induce intussusception. If surgery is performed either for a complication of the lipoma or an unrelated condition, local excision is adequate treatment.

HAMARTOMAS

Peutz-Jeghers syndrome (PJS) is an autosomal dominant condition characterized by multiple gastrointestinal hamartomas and mucocutaneous pigmentation. The polyps arise predominantly in the jejunum and ileum and often present as an intussusception. Although hamartomas rarely if ever undergo malignant transformation, the condition is associated with the development of adenocarcinoma.¹⁷ Double-balloon enteroscopy and video capsule endoscopy have provided effective screening technologies for patients with PJS. Endoscopic mucosal resection of hamartomas or polyps in patients with PJS via double-balloon enteroscopy has been described. Surveillance is recommended with endoscopic removal of lesions when they are identified. Patients who are diagnosed with PJS are at increased risk for developing a number of cancer types, including colorectal, gastric, small-bowel, ovarian/testicular, and pancreatic cancer. Patients who are diagnosed with this disease should undergo genetic counseling and have first-degree relatives screened. Screening for duodenal and small-bowel tumors in patients who are positive for the genetic mutation that causes PJS can include interval esophagogastroduodenoscopy and small-bowel contrast studies beginning in childhood (as early as age 8).²⁴ Although no consensus exists regarding the exact screening guidelines for these patients, close follow-up by a gastroenterologist is warranted given the high risk for a number of malignancies.

HEMANGIOMAS

Hemangiomas are rare lesions of the small bowel, developing predominantly in the jejunum and ileum. They are congenital lesions that grow slowly, typically coming to medical attention

in the third decade of life because of acute or chronic blood loss. Arising from the submucosal vascular plexuses, hemangiomas are classified as capillary, cavernous, or mixed depending on what size vessel primarily is affected. They are usually solitary lesions and malignant degeneration is exceedingly rare. Depending on size, hemangiomas may be locally excised or resected with a laparoscopic approach with limited small-bowel resection. Efforts to manage hemangiomas with endoscopic or operative sclerotherapy or coagulation and operative or angiographic interruption of arterial supply have been minimally successful.

MALIGNANT NEOPLASMS

Malignant neoplasms in the small bowel are either primary or metastatic. Primary malignancies include adenocarcinoma, gastrointestinal stromal tumors (GISTs), leiomyosarcoma, non-Hodgkin lymphoma (NHL), and carcinoid tumors, with rare reports of other lesions including liposarcoma, myxoliposarcoma, and lymphangiosarcoma. Metastatic tumors of the small bowel have been reported from many primary solid tumors, but melanoma and lymphoma are the most common. Compared with benign tumors, malignant lesions are more likely to present with pain, weight loss, and anorexia. Although nonspecific, these findings are more ominous than other symptoms shared with benign tumors, such as nausea and vomiting and acute or chronic blood loss. As a group, patients with malignant small-bowel tumors present at advanced stages and have a poor prognosis. High rates of metastatic spread are noted on initial surgical operation.

The diagnosis of small-bowel malignancy should prompt a thorough diagnostic evaluation. Second primary malignancies are found in 20% to 30% of patients. This association is especially relevant for carcinoid tumors, where the incidence rate of second primaries is as high as 30% to 50%. The second primary cancer may arise in any organ, but the most frequent second primary sites are the colorectum and breast.²⁹

ADENOCARCINOMA

Epidemiology

Adenocarcinoma accounts for about 30% of small-bowel tumors.¹ Like adenomas, sporadic adenocarcinomas have a predilection for the duodenum, with a marked decrease in frequency moving axially along the small bowel.³ Approximately 80% of tumors are located in the duodenum or proximal jejunum. Most studies report a slight male preference.

There are several risk factors for the development of adenocarcinoma. Malignant transformation of villous and tubulovillous adenomas is likely the most important and occurs predominantly in the periampullary region of the duodenum. Crohn disease increases the risk up to 100-fold and predisposes to cancer in the more distal small bowel in regions of dysplasia.

Clinical Presentation

The presenting symptoms of small-bowel adenocarcinoma depend on the location and size of the tumor. Because tumors tend to arise in the proximal small bowel and to encompass the bowel wall, adenocarcinomas cause obstruction with associated anorexia. The majority of tumors cause crampy abdominal pain. Periampullary duodenal adenocarcinomas may cause obstructive jaundice or pancreatitis as they grow. In this case, the physical complaints and findings help guide the direction of the diagnostic evaluation. Often, the only complaint is vague, persistent abdominal pain.

FIGURE 50.2. A 73-year-old woman who presented with gastric outlet obstruction was found on this small-bowel follow-through study to have apple-core lesion of the proximal jejunum. At exploration, she was found to have jejunal adenocarcinoma.

Diagnosis

If obstruction is present, plain abdominal films may reveal gastric distention or near-complete proximal small-bowel obstruction. More commonly, however, these films are unrevealing. For the jaundiced patient, ultrasound or abdominal CT or magnetic resonance cholangiopancreatography may demonstrate the duodenal mass and site of biliary obstruction. Esophagogastroduodenoscopy is the diagnostic modality of choice, with diagnostic rates of 85% to 90%.

Of small-bowel adenocarcinomas, 70% are polypoid, 20% are ulcerated, and 10% are infiltrative. Comparable to other segments of the gastrointestinal tract, adenocarcinomas of the jejunum and ileum are usually annular constricting tumors seen as apple-core lesions, as demonstrated on luminal contrast studies or esophagogastroduodenoscopy (Fig. 50.2). Long lesions, especially when ulcerated, may be mistaken for lymphomas. On CT scan, adenocarcinomas may attenuate heterogeneously and have moderate contrast enhancement. Again, usually only a short segment of small bowel is involved, and occasionally they are associated with an ulcer. Despite the array of diagnostic modalities, preoperative diagnosis remains infrequent, achieved in only 20% to 50% of cancers.

Management

The only potential cure for adenocarcinoma is complete surgical resection. At operation, the resectability rate for cure approaches 60%. For proximal and midduodenal lesions, pancreaticoduodenectomy is necessary to completely resect the tumor and lymphatic basin. In the third and fourth portions of the duodenum and in the mesenteric small bowel, a segmental resection with lymphadenectomy should be performed to attempt surgical cure. In patients with metastatic or unresectable disease, palliative procedures to relieve obstruction or control hemorrhage should be considered. Segmental resection or intestinal bypass is appropriate in some patients. Duodenal obstruction may be palliated with endoscopic placement of expandable stents, although recurrent obstruction and hemor-

rhage may complicate this procedure. Consideration should be given to placement of gastrojejunal or gastrostomy tubes in patients with carcinomatosis or unresectable disease found at the time of surgery for palliative decompression or nutritional support and hydration.

Staging and Prognosis

The American Joint Committee on Cancer (AJCC) staging system for small-bowel adenocarcinoma is similar to those for gastric and colon carcinoma. The staging system applies only to adenocarcinoma of the small bowel and not to other malignant neoplasms of the small intestine. Carcinoma of the ampulla of Vater is also staged separately. As in other gastrointestinal malignancies, the tumor classification (T) describes depth of invasion, with T1 and T2 both contained within the bowel wall and T3 and T4 describing gradations of penetration through the wall. Unlike colon cancer, the node classification (N) in small-bowel carcinoma is classified only by presence or absence of lymph node metastases, and not by numbers of positive nodes. Distant metastases are classified (M). The TNM classification for small-bowel adenocarcinoma is summarized in Table 50.3. As shown, prognosis is grim for patients presenting with stage III or IV disease, the most frequent stages at diagnosis.

Factors that affect long-term survival in small-bowel adenocarcinoma vary slightly by study and tumor location. For duodenal tumors, negative resection margins and tumors in the first and second portions seem to favorably affect prognosis, whereas nodal status and size and differentiation of the tumor do not.³⁰ In contrast, ampullary tumors are associated with better prognosis if lymph nodes are not involved and the tumor does not infiltrate the pancreas.²⁶ One study evaluating prognostic factors for all small-bowel malignancies, exclusive of periampullary lesions, demonstrated poor survival in node-positive patients regardless of curative resection. Studies examining cancers of the jejunum and ileum are limited by their small sizes; however, a recent study concluded that among the factors for survival were positive margins, extramural venous spread, positive lymph nodes, and history of Crohn disease.³¹

Chemotherapy (typically 5-fluorouracil [5-FU] alone or in combination with other agents such as doxorubicin, cisplatin, mitomycin C, cyclophosphamide, and oxaliplatin) is often administered to patients with adenocarcinoma of the small intestine based on regimens administered for other gastrointestinal cancer. Unfortunately, chemotherapy and/or radiation therapy has not been shown to confer a survival advantage or prolonged disease-free interval.³¹ It should be noted, however, that no adequate clinical trials have been conducted to delineate the efficacy of adjuvant chemotherapy for adenocarcinoma of the small intestine, so at the present time it is not possible to definitively comment on its role in the treatment of small-intestinal adenocarcinoma.³²

NON-HODGKIN LYMPHOMA

- 4 NHL of the gastrointestinal tract represents 4% to 20% of all NHLs, with the gastrointestinal tract being the most common extranodal site for NHL to occur. In the gastrointestinal tract, NHL is most commonly located in the stomach, followed by the small bowel and then the colon. Of all gastrointestinal NHLs, 25% to 35% of cases occur within the small bowel. The distribution pattern is marked by relative sparing of the duodenum and equal frequency in the jejunum and ileum.

Many retrospective reviews of small-bowel cancer exclude primary NHL from analysis because of the difficulties in differentiating primary small-bowel lymphomas from those that originated outside of the gastrointestinal tract. Specific criteria must be met to establish the diagnosis of primary gastrointestinal NHL. In order to definitively make this diagnosis, there must be no evidence of lymphoma outside of the gastrointestinal tract.

TABLE 50.3

STAGING

TNM CLASSIFICATION AND STAGING OF SMALL-BOWEL ADENOCARCINOMA

■ TNM	■ CARCINOMA PENETRATION	■ STAGE	■ 5-YEAR SURVIVAL RATE
Tx	Unknown primary		
T0	No evidence of primary		
Tis	Carcinoma in situ	0	
T1	Tumor invades lamina propria or submucosa	I	70%
T2	Tumor invades muscularis propria		
T3	Tumor extends <2 cm into subserosa or into nonperitonealized perimuscular tissue (mesentery in jejunum or ileum, retroperitoneum in duodenum)	II	50%
T4	Tumor penetrates visceral peritoneum or directly invades >2 cm into adjacent structures		
Nx	Regional lymph nodes not assessed		
N0	No regional lymph node involvement		
N1	Regional lymph nodes involved		
Mx	Distant metastases not assessed	III	20%
Mo	No distant metastases		
M1	Distant metastases present	IV	10%

On physical examination, there should be no superficial adenopathy, and chest radiograph (CT or x-ray) should reveal no mediastinal adenopathy. Peripheral blood cell counts must be normal, and there may be no evidence of splenic or hepatic involvement. Finally, at laparotomy, disease must be restricted to the primary tumor with mesenteric lymph node involvement.

Multiple histologic variations of lymphoma exist, showing significant geographic variability. The majority of primary intestinal NHLs are of the B-cell type, with T-cell lymphoma comprising only 10% to 25% of cases. Further classifications of B-cell and T-cell tumors have been proposed, but none has been uniformly adopted. A significant number of gastrointestinal lymphomas appear to be low-grade lymphomas derived from mucosal-associated lymphoid tissue. These lymphomas arise predominantly in the stomach but also occur in the small bowel. In the stomach they are associated with *Helicobacter pylori* infection and may regress with treatment of this infection. In the small bowel these low-grade lymphomas should be resected. T-cell lymphomas tend to have a worse prognosis than B-cell tumors.

Clinical Presentation

Similar to other small-bowel malignancies, the majority of patients with NHL present with abdominal pain that is non-specific and unlocalized. Malabsorption, obstruction, and evidence of a palpable mass may be present. Although rare, perforation is a more common presentation for gastrointestinal NHL than for adenocarcinoma, possibly related to a lack of a vigorous desmoplastic response in lymphoma. Signs that are common in nodal lymphoma, such as adenopathy and splenomegaly, are unusual in primary gastrointestinal NHL.

Diagnosis

Most small-bowel lymphomas will be demonstrable on CT scan, as these lymphomas may grow to be quite large. CT scan will demonstrate the mass as well as marked luminal dilata-

tion, bowel wall thickening, and displacement of neighboring loops (Figs. 50.3 and 50.4). Short strictures are more suggestive of adenocarcinoma but may occasionally be seen with lymphoma. Small-bowel follow-through will reveal multifocal lesions in 10% to 25% of patients. To make a tissue diagnosis, biopsies must be obtained from the submucosa, as the overlying mucosa often demonstrates no evidence of tumor infiltration. CT-guided biopsy may be diagnostic, although proximal lesions are best diagnosed with endoscopic submucosal biopsy.

Staging and Prognosis

Unlike other solid tumors of the gastrointestinal tract, the TNM system does not apply to staging of gastrointestinal NHL. Rather, staging is based on site involvement, outlined in Table 50.4. Like tumors elsewhere in the small bowel, lymphomas are typically diagnosed late, with almost half of patients presenting as stage III or IV disease. Fewer than 30% of patients have surgically resectable tumors. Patients with stage I tumors have a 40% to 60% 5-year survival, whereas those with stage II disease have a 20% 5-year survival. The long-term survival for patients with stages III and IV disease remains negligible, despite the aggressive use of chemoradiation therapy.

Treatment

With no randomized series and small numbers of cases at single institutions, the optimal treatment of gastrointestinal NHL remains controversial. Previously, surgical resection of localized gastrointestinal lymphomas followed by systemic chemotherapy was considered to be standard first-line therapy.³³⁻³⁵ The data regarding the efficacy of primary surgical therapy with or without adjuvant chemotherapy versus systemic therapy alone are limited since gastrointestinal lymphomas are relatively rare. In many case series reporting outcomes after surgical resection of gastrointestinal lymphoma, the diagnosis of lymphoma was not known preoperatively and discovered only after intervention for a symptomatic small-bowel lesion. It is not clear, however,

FIGURE 50.3. This small-bowel follow-through was performed on a 71-year-old man with chronic symptoms of partial small-bowel obstruction. It demonstrated a persistently dilated small-bowel loop in the terminal ileum with a thickened wall. The computed tomography scan in Figure 50.4 was obtained.

whether surgery should be the first line of treatment if a diagnosis of lymphoma can be made prior to any operative interventions. Indeed, for most lymphomas, systemic therapy and/or radiation has been considered to be standard first-line therapy, rather than surgical resection, because lymphoma is recognized to have the potential for systemic dissemination. For other gastrointestinal lymphomas, such as gastric lymphoma, chemotherapy and/or radiation is now considered to be the first-line therapy of choice, with surgical interventions being reserved for complications such as bleeding, perforation, obstruction, or failure to respond. Indeed, non-Hodgkin, diffuse B-cell lymphoma is the most common type of gastric lymphoma, and it is now

FIGURE 50.4. The computed tomography scan similarly demonstrated a thickened ileal loop with dilatation. No adenopathy was noted. At surgery, the patient was found to have a primary lymphoma of the small bowel.

TABLE 50.4 **STAGING**

STAGING OF NON-HODGKIN LYMPHOMA OF THE GASTROINTESTINAL TRACT

■ STAGE	■ EXTENT OF DISEASE
I	Tumor confined to the gastrointestinal tract, either as single primary site or multiple noncontiguous lesions
II	Tumor extends from primary gastrointestinal site, either to lymph nodes or direct invasion. Confined to below the diaphragm
III	Tumor penetrates serosa to involve adjacent structures
II ₁	Local nodal involvement
II ₂	Distant nodal involvement
III	Evidence of supradiaphragmatic disease
IV	Disseminated disease above and below the diaphragm

routinely treated primarily with anthracycline-based chemotherapy regimens, in combination with monoclonal-based antibody therapies such as rituximab and/or irradiation.³⁶ The majority of small-bowel lymphomas are also large-cell, non-Hodgkin, B-cell-type lymphomas. Although they may appear to be localized, biologically these tumors tend to be more aggressive and often require systemic therapy for definitive management. Increasingly, systemic therapy is considered to be the mainstay for management of these lesions. Surgical intervention can still be considered for patients who are refractory to chemotherapy or as primary therapy for localized small-bowel lymphoma with favorable histology.³⁷ Decisions regarding the management of small-bowel lymphomas that do not require emergent surgical management should be made in a multidisciplinary setting with input from surgeons, medical oncologists, and pathologists, as there is currently no definitive consensus regarding standard first-line therapy for small-bowel lymphomas.^{3,37–39}

CARCINOID TUMORS

- 5 Carcinoids are indolent malignant neuroendocrine tumors that arise from the enterochromaffin cells at the base of the crypts of Lieberkühn. These cells are part of the amine precursor uptake and decarboxylation (APUD) system and can secrete peptides responsible for the carcinoid syndrome. Although 80% of carcinoids arise in the gastrointestinal tract, 10% of primary carcinoids occur in the bronchus or lung. Other sites, such as the ovaries, testicles, pancreas, and kidney, are far less common. Within the gastrointestinal tract, carcinoids are most often identified in the appendix, followed by the small bowel, which harbors approximately 30% of all gastrointestinal carcinoids. Almost half of these arise in the distal 2 feet of ileum.

A recently published series (the largest to date) evaluated all small-bowel malignancies reported to the National Cancer Database from 1985 to 2005. Analysis of 67,000 patients with small-intestinal tumors revealed that the incidence of small-bowel cancer of all histologies has increased, but most of the change is a result of a more than fourfold increase in the incidence of carcinoid tumors. In this particular series, carcinoid tumors accounted for the majority of small-intestinal cancers, surpassing adenocarcinoma of the small intestine.³ Of all the patients evaluated, 25,339 patients (37.4%) had carcinoid tumors and 25,053 patients (36.9%) had adenocarcinomas. In various series, carcinoid tumors comprise 30% to 35% of small-bowel neoplasms, and carcinoids are found slightly

more often in men than in women.^{3,40} The mean age of presentation is 60 years. The tumors are frequently asymptomatic; in fact, the autopsy rate in one study was over 2,000 times that of the annual incidence rate, indicating the potential for long-standing slow growth. When symptomatic, carcinoids typically present with pain or obstructive symptoms. Because these tumors are typically slow growing, symptoms may be present for 2 to 20 years prior to diagnosis. Ulceration is rare in carcinoids, so gastrointestinal bleeding is uncommon. Patients present with carcinoid syndrome in up to 40% of cases and only in the presence of symptoms of carcinoid syndrome is the diagnosis consistently made preoperatively.

There are five histologic patterns that correlate embryologically with the location of the tumor.⁴¹ The foregut, or duodenal, lesions usually demonstrate a trabecular or ribbon pattern. An insular pattern predominates in the midgut or small-bowel lesions, and a mixed pattern is typical of the hindgut or colorectal lesions. The least common patterns are glandular or tubular and undifferentiated, both of which have a much poorer prognosis than the three more common variations. The histologic pattern does not affect treatment, but with other factors, appears to impact on long-term survival.

Clinical Presentation and Diagnosis

The most common presenting symptom for patients with a small-bowel carcinoid tumor is abdominal pain. As carcinoids grow, the polypoid lesions may serve as a lead point for intussusception. Intussusception is characterized by intermittent abdominal symptoms and signs of obstruction. Abdominal films often demonstrate a distal small-bowel obstruction. The CT findings of intussusception are distinctive, demonstrating a multilayer ringed structure in the ileocolic region (Figs. 50.5 and 50.6).

Unlike in the appendix where multicentricity is rare, carcinoids of the small bowel are multiple 30% to 40% of the time.⁴² In addition, 30% to 50% of small-bowel carcinoids are associated with second primary malignancies, most frequently of the breast and colon. Gastrointestinal carcinoids have the capacity to elicit a marked desmoplastic reaction. The mesentery of the small bowel becomes fibrotic and foreshortened, leading to kinking of the bowel or even intestinal ischemia as a result of sclerosis of the mesenteric blood vessels. The exact mechanism of this fibrosis, which is not only peritumoral but also distant in the heart and lungs, is still unknown.⁴³ This finding is readily identified on CT scan⁴⁴ and is sometimes

FIGURE 50.5. A 63-year-old man presented with a short history of abdominal pain that he described as similar to his pancreatitis pain. A computed tomography scan demonstrated an ileal carcinoid tumor as the lead point for an intussusception into the cecum.

FIGURE 50.6. Resection of ileocolic segment of bowel in the patient shown in Figure 50.5 to have an intussusception. Here carcinoid tumor can be seen as the lead point for intussusception through the ileocecal valve.

associated with calcifications while the small bowel appears fixed and angulated.

Stage and Prognosis

Tumor size is proportional to the risk for metastatic spread at initial diagnosis and must be considered in directing surgical strategies. In comparison to appendiceal carcinoids, which may cause appendicitis at a small size prior to lymph node metastasis, small-bowel lesions often remain asymptomatic long enough to allow not only lymph node spread but also hepatic metastasis. For lesions smaller than 1 cm, there is a 20% to 30% incidence of nodal and hepatic spread. Tumors 1 to 2 cm in size have nodal spread in 60% to 80% and hepatic disease in 20%. The rate of nodal and hepatic metastasis for tumors larger than 2 cm is greater than 80% and 40% to 50%, respectively.⁴⁰ These figures must guide the choice of operation. Whereas a small lesion less than 1 cm may be adequately treated with local excision, anything larger must be presumed to be metastatic and a wide resection with lymphadenectomy and careful examination of the liver is necessary.

Carcinoid Syndrome

Carcinoid syndrome refers to vasomotor, gastrointestinal, and cardiac manifestations induced by systemic circulation of a variety of peptides elaborated by carcinoid tumors. The amine precursor uptake and decarboxylation cells of carcinoid tumors can produce vasoactive products including serotonin, histamine, kallikrein, bradykinin, and prostaglandins, although the specific mediator or mediators of the syndrome remain unknown. Carcinoid syndrome is most reliably confirmed by finding elevated 24-hour 5-hydroxyindoleacetic acid (5-HIAA) urinary excretion, the primary stable metabolite of serotonin.

Attacks are initiated by stimuli including stress, alcohol, a large meal, or sexual intercourse, all of which manipulate the liver in some capacity. Flushing is the most common finding and affects approximately 80% of syndrome patients. The flush varies slightly by the location of the tumor, but in midgut carcinoids the flush is usually short-lived, lasting 5 to 10 minutes. Classically, the erythematous flush begins on the face and spreads to the trunk and limbs. Diarrhea, found in 75% of patients, seems to be caused by serotonin release. The diarrhea is intermittent, watery, and at times explosive. It may be associated with abdominal cramps and the patient may experience a certain degree of malabsorption. Cardiac manifestations are present in 60% to 70% of patients due to tricuspid and pulmonary valve fibrosis, possibly secondary to high levels of 5-hydroxyindoleacetic acid. As the disease progresses, the fibrotic plaque stiffens, leading eventually to right heart failure.

Patients with gastrointestinal carcinoid tumors who present with carcinoid syndrome have metastatic disease in either the liver or retroperitoneum. The liver contains large amounts of monoamine oxidase, which deactivates serotonin, the major effector hormone. Hence, to develop carcinoid syndrome, a patient must either have tumor in a location that does not primarily drain into the portal circulation, such as a bronchial carcinoid or retroperitoneal tumor, or have hepatic metastases of a magnitude that overwhelms the capacity of monoamine oxidase to break down serotonin. The bioactive products from a small volume of hepatic metastases may be cleared by the hepatocytes, but a larger tumor burden allows release of these products into the hepatic veins and the systemic circulation. It follows that patients with bronchial and ovarian carcinoids, or abdominal disease that has penetrated the retroperitoneum, which drains directly into the systemic circulation, can manifest carcinoid syndrome from primary disease. Patients with gastrointestinal carcinoids, which drain into the portal circulation, must have metastatic disease prior to the development of the syndrome.

Management of patients with carcinoid syndrome may be approached surgically, radiologically, and medically, and often requires a combination of all three modalities. Surgical debulking of extensive hepatic disease with segmental resection or ablation or formal hepatic resection for resectable metastases may improve symptoms and prolong life. For patients with residual abdominal tumor and hepatic metastases, 5- and 10-year survival rates approached 60%, so although in general the initial surgery should involve attempts to debulk as much tumor as possible, it must also avoid catastrophic injuries such as those to the superior mesenteric vessels that may lead to short-gut syndrome.⁴⁵ Hepatic artery embolization or radiofrequency ablation may be more appropriate for widespread hepatic metastases and in small series have been shown to give marked symptomatic relief and durable tumor control.⁴⁶⁻⁴⁸ Medical therapy relies primarily on the use of a variety of somatostatin analogues (octreotide) including short- and long-acting peptides for relief of carcinoid syndrome symptoms. Carcinoid tumors express somatostatin receptors and the somatostatin analogues inhibit vasoactive peptide release from these tumors. Efficacy of treatment can be documented by following excretion of the tumor marker 5-hydroxyindoleacetic acid. Palliation of symptoms is effective in 90% of patients with octreotide and some studies have even demonstrated a tumorostatic or tumor reduction effect after the administration of somatostatin, although these latter findings have not been consistently observed. Serotonin antagonists are useful in the management of gastrointestinal symptoms including rapid transit and diarrhea.

Chemotherapeutic agents for the treatment of metastatic carcinoid tumor have been used singly and in combination in an effort to halt progression of disease as well as to promote tumor regression; however, objective responses to chemotherapy are limited. Studies testing single-agent chemotherapy (5-FU, doxorubicin, actinomycin D, dacarbazine, and streptozocin) demonstrated no beneficial effect.^{48a,49} Combination regimens have also been studied in phase II trials including 5-FU and streptozocin with or without cyclophosphamide. Responses to streptozocin-based combined chemotherapy regimens were evident in approximately 8% to 25% of patients.⁴⁹ Cytotoxic treatment in patients with malignant carcinoid tumors. Preliminary reports on the use of novel targeted radiotherapeutic agents have been presented. These are synthetic somatostatin analogues that can bind to somatostatin receptors on carcinoid tumors with high affinity. After binding receptors on the tumor, the ligand-receptor complex is internalized. These analogues can be conjugated to radioactive surface isotopes, effectively generating a “smart bomb” that can theoretically deliver radiation specifically to carcinoid cells. In an early-phase study, ¹¹¹indium-labeled pentetreotide induced a greater tumor regression response compared to unlabeled somatostatin analogue.⁵⁰ Further investigations are ongoing.

GASTROINTESTINAL STROMAL TUMORS

Although GISTs are the most common nonepithelial cell tumors of the small bowel, they are rare tumors of the gastrointestinal tract, representing only about 5,000 cases nationwide per year.⁵¹ Approximately 25% of GISTs arise in the small bowel, with 50% gastric, 15% rectal, and 10% colonic in origin.⁵² GISTs are diagnosed equally in men and women, with a median age at onset of 64 years. Arising from the interstitial cell of Cajal, the pacemaker cells of the gastrointestinal tract situated between the intramural neurons and the smooth muscle cells, GISTs are characterized by the presence of activating c-kit mutations, a transmembrane receptor tyrosine kinase involved in the regulation of cellular proliferation, apoptosis, and differentiation. More than 95% of GISTs express kit (CD117) mutations.⁵¹ This molecular marker allows for distinction of GISTs from histologically similar mesenchymal tumors of the small bowel including leiomyomas, leiomyosarcomas, and schwannomas. This molecular feature has led to reclassification of up to 70% of small-bowel tumors as GISTs that had previously been classified as a variety of mesenchymal tumors. Those GISTs that do not express c-kit mutations may express a mutation in another tyrosine kinase receptor, platelet-derived growth factor receptor- α (PDGFR- α).⁵³ Present in approximately 5% to 7% of GISTs, these activating mutations also result in abnormal cellular proliferation.

Like other primary small-bowel tumors, GISTs are characterized by indolent clinical symptoms including vague abdominal pain, weight loss, and occult gastrointestinal bleeding. Although acute hemorrhage, perforation, or obstruction may lead to an emergency presentation, GISTs may grow to a massive size prior to surgical presentation. Usually they grow insidiously as extraluminal masses from their submucosal origin in a noninvasive manner, characteristically pushing adjacent organs away from the expanding mass.

Diagnostic strategies are the same as for other tumors of the small bowel. Given the propensity of GIST to grow to a large size prior to diagnosis, CT scan is most likely to be the initial positive test. A characteristic finding is the presence of a large space-occupying mass, occasionally with calcification and hypervascularity and often with evidence of central necrosis and compression of adjacent organs (Fig. 50.7A). Smaller tumors are detected with esophagogastroduodenoscopy in the stomach and duodenum and with video capsule endoscopy or double-balloon enteroscopy in the small bowel. ¹⁸F-fluorodeoxyglucose (¹⁸F-FDG) positron emission tomography (PET) testing has also been utilized for assessing response to adjuvant therapies but is not employed generally for initial staging of the disease.⁵¹

All GISTs should be considered to be malignant.⁵⁴ Malignant potential is based on two major criteria, as reported from the National Institutes of Health consensus workshop: tumor size and mitotic rate (Table 50.5). Biologically aggressive tumors are large lesions with a high mitotic index, whereas tumors with benign features are small and exhibit a low mitotic index. Tumors are thus classified into very-low- to high-risk lesions for malignant potential, a classification that has prognostic significance. Additional reports have suggested negative factors for prognosis including high Ki-67 index and male gender, but these parameters have not consistently been predictive.⁵¹

Treatment

Surgery is the primary therapeutic option with the goal being complete resection. Preoperative biopsy is controversial, and a presumed diagnosis of GIST is enough to warrant surgery if the disease appears resectable. At operation, wide local excision of the primary tumor with in continuity resection of adherent organs is appropriate to attain curative resection

FIGURE 50.7. A: Computed tomography image of a 76-year-old man with abdominal distention demonstrating a complex abdominal mass with varying degrees of thickness, central necrosis, and compression of adjacent organs. This was found to be a gastrointestinal stromal tumor with markedly increased mitotic activity. B: Intraoperative photograph of the same patient, showing displacement of adjacent organs.

(Fig. 50.7B). For small and localized lesions, laparoscopic resection appears to be safe and effective. Lymph node metastases are rare, but if bulky mesenteric adenopathy is noted, wide mesenteric resection is indicated.

Molecular Therapeutics and Gastrointestinal Stromal Tumor

- 6 The discovery of the pathognomonic constitutively activated mutations in the tyrosine kinases c-kit and PDGFR- α in GIST has stimulated development of therapeutic agents targeting these moieties. Activation of c-kit leads to phosphorylation of a receptor substrate protein initiating an intracellular phosphorylation cascade. This cytoplasmic cascade ultimately leads to nuclear activation of transcription events culminating in cell proliferation and survival. Imatinib mesylate is a small molecule that occupies the adenosine triphosphate-binding pocket of the c-kit kinase domain, blocking phosphorylation of the receptor and intracellular signaling. This binding arrests cellular proliferation and survival signaling.

Imatinib is now commonly used to manage unresectable or metastatic GISTs, or as adjuvant therapy in those at high risk for recurrence. The American College of Surgeons Oncology Group (ACOSOG) conducted a phase II intergroup trial

(Z9000) examining adjuvant imatinib (400 mg/d for 12 months) after complete macroscopic resection in patients with high-risk primary GISTs (five or more tumors, tumor size ≥ 10 cm, or intraperitoneal tumor rupture or hemorrhage). One hundred and six patients were treated using imatinib (400 mg/d) for 1 year. Eighty three percent of the accrued patients were able to complete the full year of imatinib therapy. Three-year survival in these imatinib-treated patients was 97%, which was concluded to be better than historic controls. A separate double-blind, phase III ACOSOG trial (Z9001) testing the efficacy of adjuvant imatinib preventing GIST recurrence in patients with completely resected GISTs at least 3 cm in size had to be terminated at a median follow-up of 13 to 14 months due to significantly better recurrence-free survival in the treatment versus placebo group (97% vs. 83%).⁵⁵ Imatinib is well tolerated and highly effective for patients with metastatic GISTs. Although complete regression of tumor is rare, partial regression of disease and arrest of progression of disease can be achieved for durable intervals with continuous treatment in up to 80% of patients.⁵¹ Efficacy of treatment can be predicted and followed using ¹⁸F-FDG PET scanning; these highly biologically active tumors will become metabolically silent with imatinib therapy in those patients with responsive tumors. With greater clinical experience with imatinib, resistant clones have been identified with eventual progression of disease. For these patients, a newer

TABLE 50.5

MALIGNANT POTENTIAL AND PROGRESS OF GASTROINTESTINAL STROMAL TUMORS

■ RISK CLASSIFICATION	■ SIZE	■ MITOTIC RATE	■ 10-YEAR SURVIVAL
High	Any size >10 cm >5 mm	>10/50 HPF Any rate >5/50 HPF	30%
Intermediate	5–10 cm <5 cm	<5/50 HPF 6–10/50 HPF	60%
Low	2–5 cm	<5/50 HPF	75%
Very low	<2 cm	<5/50 HPF	80%
Normal population	—	—	80%

HPF, high power field.

multitarget receptor tyrosine kinase inhibitor, sunitinib, has recently been introduced for clinical trials. This inhibitor has a broader spectrum of activity than imatinib and has shown early promise in patients with progression of disease on imatinib or in those relatively few patients who cannot tolerate imatinib.⁵⁴

Use of imatinib in the neoadjuvant setting for unresectable or locally aggressive tumors has been reported recently⁵⁶ with response rates near 75%,⁵¹ and about 25% of unresectable lesions are converted to resectable lesions.⁵⁶ The efficacy of imatinib in the adjuvant setting for high-risk or partially resected tumors is also being evaluated in ongoing trials.

METASTATIC LESIONS TO THE SMALL BOWEL

The small bowel is the site of metastatic disease from multiple other primary sites. Metastatic spread can occur by direct invasion, hematogenous spread, or intraperitoneal seeding. Direct invasion from a colon or pancreatic cancer represents the most common mode of involvement. Hematogenous spread arises most frequently from bronchogenic or breast carcinoma or malignant melanoma. Peritoneal seeding has been documented from primary tumors of the stomach, liver, ovary, appendix, and colon.

A CT scan often demonstrates not only the degree of involvement of the small bowel but also the primary tumor. In metastatic small-bowel tumors, one may see bowel wall thickening as well as lesions in the mesentery or retroperitoneal fat. For small lesions, CT scan may be negative, while video capsule endoscopy or double-balloon enteroscopy may reveal a luminal mass. Carcinomatosis may be difficult to identify even on body CT imaging.

Optimal management is based on clinical criteria. Palliative intestinal resection or bypass to relieve hemorrhage, obstruction, or pain is indicated except in the most terminal stages of disease. Case reports of prolonged survival after intestinal resection of solitary metastases have been reported, although progression of metastatic disease is more common.⁵⁷

Management of patients with carcinomatosis, regardless of tumor origin, remains difficult. Palliative measures to maintain intestinal continuity and liberal use of decompressive gastrostomy tubes are indicated.

CHAPTER 51 ■ PANCREAS ANATOMY AND PHYSIOLOGY

TAYLOR S. RIALI

KEY POINTS

- 1 The pancreas is both an endocrine and exocrine organ.
- 2 Congenital anomalies of the pancreas largely result from failure of rotation or fusion of the ventral and dorsal pancreatic buds.
- 3 The two major components of the exocrine pancreas, the acinar cells and the ductular network, constitute 80% to 90% of the pancreatic mass, whereas the endocrine pancreas constitutes only 2% of the pancreatic mass.
- 4 The pancreatic islets of Langerhans are composed of four major cell types—alpha (A), beta (B), delta (D), and pancreatic polypeptide (PP or F) cells, which secrete glucagon, insulin, somatostatin, and PP, respectively.
- 5 B cells constitute 70% of the islet mass.
- 6 The different types of islet cells are not evenly distributed throughout the pancreas, so resection of different parts of the pancreas has differing endocrine effects.
- 7 Knowledge of the relationship of the pancreas to surrounding structures including the stomach, duodenum, distal bile duct, hepatic arterial blood supply, splenic artery and vein, celiac axis, superior mesenteric artery and vein, portal vein, spleen, adrenal glands, colon, and kidneys is critical in preventing injury to these structures during pancreatic surgery.
- 8 Progressive destruction of the afferent sensory fibers occurs during recurrent episodes of pancreatitis, which contributes to chronic pain.
- 9 The location within the pancreas, the pancreatic blood supply, and lymphatic drainage of the pancreas dictate the operation performed in patients with pancreatic malignancies.
- 10 Secretin is the major stimulant for pancreatic bicarbonate secretion, whereas pancreatic enzyme secretion is regulated through hormonal (cholecystokinin) and neural factors.
- 11 Somatostatin inhibits nearly all peptide hormones as well as gastric, pancreatic, and biliary secretions.
- 12 Tests of pancreatic exocrine function include the secretin test, 24-hour fecal fat determination, dimethadione (DMO) test, Lundh test meal, triolein breath test, and para-aminobenzoic acid (PABA) test. These tests help differentiate steatorrhea due to pancreatic insufficiency from other digestive disorders.

The pancreas is an elongated digestive organ that lies transversely in the retroperitoneum at the level of the second lumbar vertebra. It is a glandular organ that has both exocrine and endocrine function. The exocrine pancreas is composed of acinar cells and ductal networks that function to deliver alkaline solution (pH >8.0) containing over 20 enzymes and zymogens to the small intestine daily. The pancreatic secretions provide the optimal pH for the enzymes and zymogens to carry out the major digestive activity of the small intestine.

The endocrine pancreas is composed of islets of Langerhans. The islets secrete hormones including insulin, glucagon, and somatostatin directly into the bloodstream in endocrine fashion. These hormones regulate glucose homeostasis and also play a role in the complex regulation of pancreatic secretion and digestion.

The pancreas is divided anatomically into four parts: the pancreatic head, neck, body, and tail (Fig. 51.1). The pancreatic head includes the uncinate process, which is an extension of the pancreatic head wrapping posterior to the superior mesenteric vessels. An understanding of the close relationship of the pancreas to adjacent organs (duodenum, stomach, spleen, transverse colon, bile duct, and left adrenal gland) and major vessels (celiac axis, superior mesenteric artery, superior mesenteric vein, splenic artery and vein, portal vein, inferior mesenteric vein, and vena cava) is critical when performing surgical procedures on the pancreas. In addition, understanding of the embryology is critical for recognizing congenital anomalies, understanding their significance, and treating them appropriately. Knowledge of the normal pancreatic physiology provides insight into the pathologic processes

and subsequent treatments that can affect the normal function of the pancreas.

EMBRYOLOGY

Normal Pancreatic Embryology

During the fifth week of gestation, the pancreas begins forming at the junction of the foregut and midgut. The formation begins as two endodermal pancreatic buds, the dorsal bud and the ventral bud, which eventually fuse to form the pancreas (Fig. 51.2). Both the acinar cells and islet cells differentiate from the endodermal cells found in the embryonic buds. The endocrine function of the pancreas begins between 10 and 15 weeks' gestation, whereas the exocrine function does not begin until after birth.

The dorsal and ventral buds are composed of endoderm covered in splanchnic mesoderm. The splanchnic mesoderm eventually develops into the dorsal and ventral mesentery. The dorsal bud forms first and is larger. It ultimately forms much of the head, body, and tail of the pancreas. As the duodenum grows and rotates, the ventral bud rotates clockwise (Fig. 51.2) and fuses with the dorsal bud, forming the uncinate process and inferior head of the pancreas. In the majority of cases, the duct in the ventral bud fuses with the duct in the dorsal bud to become the main pancreatic duct (duct of Wirsung), which drains the majority of the pancreas into the duodenum through the major papilla, or ampulla of Vater. The proximal duct of the dorsal bud forms the lesser or minor pancreatic duct

FIGURE 51.1. Relationship of the pancreas to the duodenum and extrahepatic biliary system. The head of the pancreas lies within the C loop of the duodenum. The common bile duct courses through the head of the pancreas, emptying into the duodenum at the greater duodenal papilla (ampulla of Vater). (After Woodburne RT. *Essentials of Human Anatomy*. New York: Oxford University Press; 1973.)

(duct of Santorini), which drains into the duodenum through the minor papilla superior to the major papilla.

Surgical Significance of Abnormalities during Pancreatic Development

- 2 Abnormalities in the rotation and fusion of the pancreas during embryonic development can result in specific congenital anomalies that have surgical significance (Table 51.1). Approx-

imately 60% of the time, rotation and fusion occur normally, resulting in the classic anatomy seen in Figure 51.3A. The dorsal and ventral ducts fuse to form the main pancreatic duct, which drains the majority of the pancreas into the ampulla of Vater. The lesser duct, formed from the proximal duct of the dorsal bud, drains into the duodenum at the minor papilla.

In 30% of cases, the ventral and dorsal ducts fuse and drain normally into the duodenum at the ampulla of Vater. However, there is atrophy of the accessory or minor duct with a blind end and no minor papilla, or drainage into the duodenum (Fig. 51.3B). As this blind duct still communicates with

TABLE 51.1

CONGENITAL DISORDERS RESULTING FROM ABNORMALITIES IN THE ROTATION OR FUSION OF THE DEVELOPING PANCREAS

■ DISORDER	■ DESCRIPTION	■ PRESENTATION	■ TREATMENT
Pancreas divisum	The lesser duct drains the entire pancreas through minor papilla; caused by incomplete fusion of the ventral and dorsal pancreatic ducts during development	Often asymptomatic Adults: recurrent acute pancreatitis, chronic pancreatitis, or chronic abdominal pain	Operative or endoscopic sphincteroplasty of the minor papilla and accessory duct in symptomatic patients
Annular pancreas	Thin band of pancreatic parenchyma surrounding duodenum and causing varying degrees of duodenal stenosis; caused by abnormal fusion of ventral bud to duodenum, leading to improper rotation of ventral bud ^a	In utero: polyhydramnios Infancy: duodenal obstruction, low birth weight, feeding intolerance Adults: often asymptomatic and found incidentally	Duodenal bypass (duodenoduodenostomy or gastrojejunostomy)
Heterotopic pancreas	Functional pancreatic tissue found in locations outside the pancreas including, but not limited to, the stomach, duodenum, ileum, umbilicus, colon, appendix, and gallbladder; usually submucosal	Often an incidental finding Can present with ulceration, obstruction, intussusception	Treatment directed at presenting symptoms

^aIkeda Y, Irving IM. Annular pancreas in a fetus and its three-dimensional reconstruction. *J Pediatr Surg* 1984;19(2):160–164.

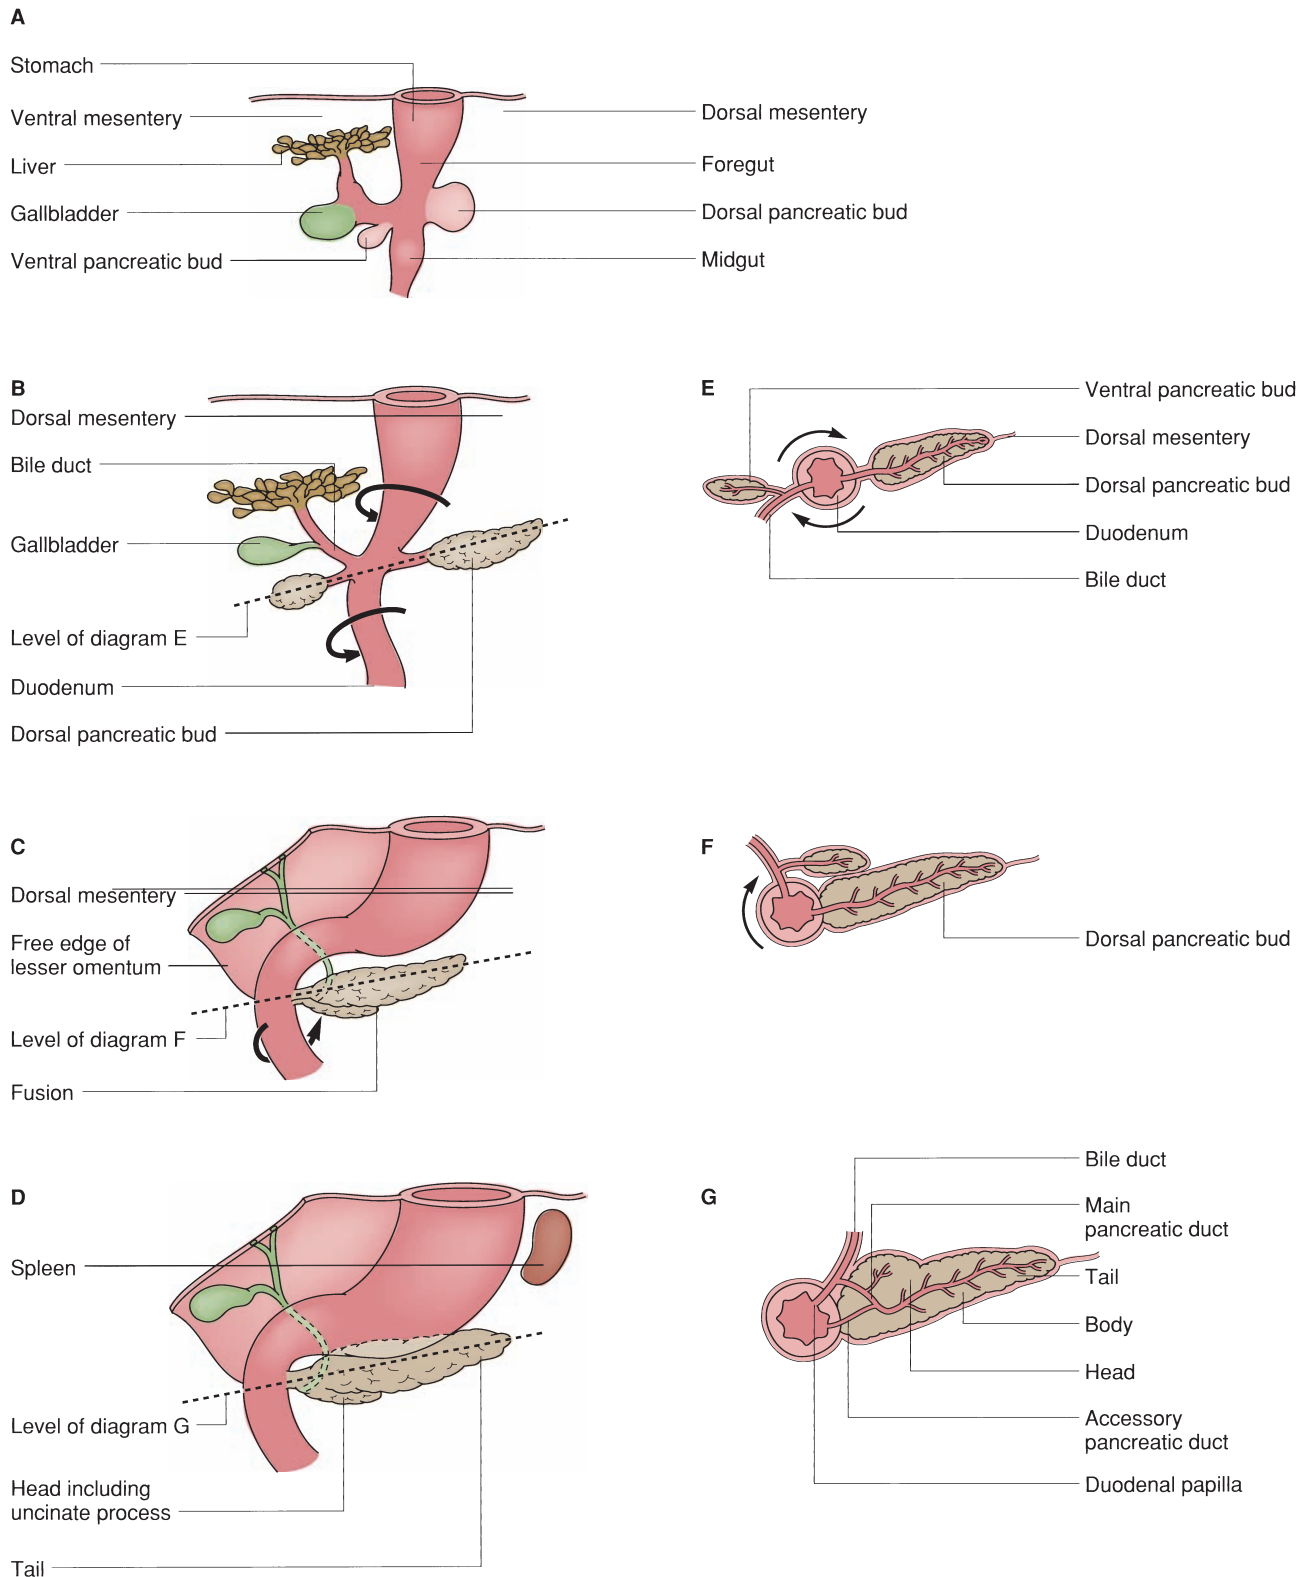

FIGURE 51.2. A–D: Schematic drawings of the successive stages in the development of the pancreas from the fifth through the eighth weeks. E–G: Diagrammatic transverse sections through the duodenum and the developing pancreas. Growth and rotations (arrows) of the duodenum bring the ventral pancreatic bud toward the dorsal bud and they subsequently fuse. The bile duct initially attaches to the ventral aspect of the duodenum and is carried around to the dorsal aspect as the duodenum rotates. The main pancreatic duct is formed by the union of the distal part of the dorsal pancreatic duct and the entire ventral pancreatic duct. (After Moore KL. *The Developing Human*, 3rd ed. Philadelphia, PA: WB Saunders; 1982.)

FIGURE 51.3. Anatomic configuration of the intrapancreatic ductal system. The classic anatomy is present in 60% of cases, where the accessory duct drains into the minor papilla and the main duct drains into the ampulla of Vater. The accessory pancreatic duct is blind and does not drain into the duodenum in 30% of cases. A lack of communication between the two ducts, which occurs in 10% of cases, is referred to as *pancreas divisum*. When this occurs, the main pancreatic duct drains into the duodenum through the minor papilla. (After Silen W. Surgical anatomy of the pancreas. *Surg Clin North Am* 1964;44:1253.)

the main pancreatic duct, this is of little to no clinical significance and most often found only at autopsy.

In 5% to 14% of cases, the fusion of the ventral and dorsal pancreatic ducts is incomplete (*pancreas divisum*, Fig. 51.3C).¹⁻³ As a result, the lesser duct drains the majority of the pancreas into the duodenum through the minor papilla. Only the small remnant duct of the ventral bud drains the uncinate process into the duodenum via the ampulla of Vater. *Pancreas divisum* is often asymptomatic. Whether this anomaly is causative in producing pancreatitis and abdominal pain is unclear.^{1,4,5} However, there is evidence that inadequate drainage of the pancreas associated with mucosal stenosis of the minor papilla is associated with amylase elevations and abdominal pain.^{1,6,7} Patients can have recurrent episodes of acute pancreatitis or chronic pancreatitis with chronic pain, most often seen in young females. If no other causes of pan-

creatitis are identified and a patient has abdominal pain, elevated amylase levels, and *pancreas divisum*, this is considered causative and an endoscopic or operative papillotomy of the minor papilla and accessory duct is indicated. As most patients with *pancreas divisum* do not develop acute or recurrent pancreatitis, it is thought that stenosis at the minor papilla or a cystic dilatation of the distal dorsal duct just proximal to the papilla may be the additional factors necessary for developing pancreatitis in the setting of *pancreas divisum*.⁸

Annular pancreas is a rare congenital anomaly of the pancreas first recognized in 1818. Early autopsy and surgical series estimate the incidence to be approximately 3 in 20,000.^{9,10} However, with better imaging modalities such as computed tomography (CT), magnetic resonance cholangiopancreatography (MRCP), and endoscopy, the incidence is thought to be closer to 1 in 1,000.¹¹⁻¹³ People with annular pancreas have a

FIGURE 51.4. Annular pancreas. The ring of pancreatic tissue surrounds the duodenum. This ring contains a large duct and may be heavily fixed to the duodenal musculature. The duodenum beneath the annulus is often stenosed. As a result, dividing the ring of pancreatic tissue may not provide relief of duodenal obstruction. There is also the danger of creating a pancreatic fistula or duodenal perforation. Duodenojejunostomy bypassing the annulus is the procedure of choice for duodenal obstruction caused by annular pancreas. (After Gray SW, Skandalakis JE. *Atlas of Surgical Anatomy for General Surgeons*. Baltimore, MD: Williams and Wilkins; 1985.)

thin band of normal pancreatic parenchyma completely surrounding the second portion of the duodenum. This band is in continuity with the head of the pancreas and causes variable degrees of duodenal compression and stenosis (Fig. 51.4). In 1910, Lecco postulated that annular pancreas resulted from abnormal fusion of the ventral pancreatic bud to the duodenum, leading to improper rotation of the ventral bud around the duodenum.¹⁴

Annular pancreas represents a spectrum of disease, presenting at varying time points from in utero to adulthood. The disease differs significantly in adults and children.¹³ When annular pancreas presents in childhood, it tends to be severe, presenting at a median age of 1 day. In children it is more commonly associated with other congenital anomalies including Down syndrome, cardiac anomalies, and other intestinal anomalies. When diagnosed in utero, the most common presentation is polyhydramnios due to duodenal obstruction. Newborns present most commonly with duodenal obstruction as evidenced by low birth weight and feeding intolerance. Duodenal bypass (duodenoduodenostomy or gastrojejunostomy) is the treatment of choice in children.

Fifty percent of cases of annular pancreas occur in adults. Adults are less likely to have significant obstruction and less likely to require surgical intervention. In adults, annular pancreas is more commonly associated with pancreas divisum and pancreatic neoplasia than in children.¹³ This abnormal ring of pancreatic tissue may contain a pancreatic duct. Therefore, the surgeon must be aware of this anomaly since division of the abnormal ring can result in pancreatic fistula or obstruction of pancreatic ductal drainage.

Heterotopic pancreas is pancreatic tissue outside the bounds of the normal pancreas without anatomic or vascular connections to the pancreas itself. Heterotopic pancreas occurs in 0.5% to 14% of autopsy series. The heterotopic pancreatic tissue is functional and can occur in a variety of sites including the stomach, duodenum, ileum, umbilicus, colon, appendix, and gallbladder, and even within a Meckel diverticulum. This tissue is usually submucosal and uniformly contains acini and ducts. Up to one third contain islet cells. Heterotopic pancreas is usually an incidental finding, but can present with ulceration, obstruction, or intussusception, in which case treatment is directed at the presenting symptoms and may require resection. In incidental and asymptomatic cases, no treatment is required. The pancreas is susceptible to

the same diseases as normal pancreas and can even undergo malignant transformation.^{15,16}

STRUCTURE AND HISTOLOGY

- 3** The pancreas has two major components: the exocrine structure and the endocrine structure. The exocrine structure of the pancreas accounts for 80% to 90% of the pancreatic mass, while the endocrine structure accounts for approximately 2% of the pancreatic mass. The remainder of the pancreas is composed of extracellular matrix, blood vessels, and major ductal structures. The exocrine component secretes the enzymes responsible for digestion, and the endocrine component is critical in glucose homeostasis.

Exocrine Structure

The exocrine structure of the pancreas is composed of two main components: the acinar cells and the ductal network. The acinar cells produce and secrete the enzymes responsible for digestion. The acinar cells are pyramidal cells with an apex that faces the pancreatic ductal network. Within the apex of the cells there are numerous zymogen granules, which contain the digestive enzymes for secretion into the ductal system. There are approximately 20 to 40 acinar cells that cluster together to form the functional unit called an acinus (Fig. 51.5A, B). A second cell type in the acinus, the centroacinar cell, functions to secrete fluid and electrolytes of the correct pH into the pancreatic ductal system. The role of the ductal system is to carry the digestive secretions to the duodenum. The acinus drains into small intercalated ducts, which join to form interlobular ducts that also secrete fluid and electrolytes (Fig. 51.5A). These interlobular ducts form secondary ducts that drain into the main pancreatic ductal system and eventually the duodenum at the ampulla of Vater.

Endocrine Structure

The pancreatic islet cells are of neural crest origin and part of the family of amine precursor uptake and decarboxylation (APUD) cells. The most critical role of the pancreatic islet cells is the secretion of insulin and glucagon to maintain glucose homeostasis, although the islets secrete other hormones with varying roles in digestion. Each pancreatic islet is approximately 40 to 900 μ m and contains an average of 3,000 cells.

- 4** The islets are composed of four cell types. Alpha (A) cells secrete glucagon, beta (B) cells secrete insulin and amylin,¹⁷ delta (D) cells secrete somatostatin, and F cells secrete pancreatic polypeptide.

- 5** B cells are located centrally within the islets and constitute approximately 70% of the islet cell mass. F cells and A cells are located peripherally within the islets and constitute 15% and 10% of the islet cell mass, respectively. D cells are located both centrally and peripherally and constitute 5% of the islet cell mass.¹⁸
- 6** The distribution of endocrine cell types is not uniform throughout the pancreas. B and D cells are uniformly distributed throughout the gland. However, A cells are concentrated in the body and tail of the pancreas, and F cells are concentrated in the uncinuate process. This distribution is important clinically, since resection of different parts of the pancreas will have varying endocrine effects.

The islet cells have a rich blood supply with the afferent arteriole entering the islet in an area of discontinuity in the non-B cells surrounding the periphery. The afferent arteriole then breaks into a capillary bed within the islet and then exits the islet through an efferent arteriole (Fig. 51.6). The hormones from the islet cells are secreted directly into this rich capillary network within the islet.

FIGURE 51.5. Histologic anatomy of the acinus. **A:** Low-magnification view of a portion of the pancreas. **B:** High-magnification view of a single acinus. The acinar cells, containing zymogen granules, are pyramidal cells with an apex that faces the pancreatic ductal network. Twenty to 40 acinar cells cluster together to form the functional unit called an acinus. The centroacinar cell, also present within the acinus, functions to secrete fluid and electrolytes of the correct pH into the pancreatic ductal system. The acinus drains into small intercalated ducts, which join to form interlobular ducts that also secrete fluid and electrolytes. These interlobular ducts form secondary ducts that drain into the main pancreatic ductal system. (After Krstic RV. *Die Gewebe des Menschen und der Säugetiere*. Berlin, Germany: Springer-Verlag;1978.)

FIGURE 51.6. Diagram of a typical islet. Afferent arterioles enter the islet through discontinuities of the mantle of non-B cells and break into capillaries, most of which traverse the B-cell mass and pass through the mantle as efferent vessels. Occasionally, a capillary passes at the interface of the B cell and non-B cells and never enters the B-cell core. In larger islets, the efferent capillaries coalesce at the edge of the islet and pass along the mantle as collecting venules before draining into a vein. (After Bonner-Weir S, Orci L. New perspectives on the microvasculature of the islets of Langerhans in the rat. *Diabetes* 1982;31:883.)

PANCREATIC ANATOMY

The pancreas lies in the retroperitoneum at the level of the second lumbar vertebra. It lies obliquely and transversely from its most caudal point at the duodenal C loop on the right to its most cranial point in the splenic hilum on the left. The pancreas is composed of four anatomic parts: the head (including the uncinate process), neck, body, and tail (Fig. 51.1).

Relationship to Adjacent Structures

- 7 The understanding of the pancreatic anatomy in relation to adjacent structures is critical when performing operative procedures on the pancreas or surrounding structures including the duodenum, bile duct, and spleen. The pancreatic head, further subdivided into the head and uncinate process, is embraced by the C loop of the duodenum (Fig. 51.1). The pancreatic head is the portion of the pancreas extending to the right of the superior mesenteric vessels. The uncinate process is a projection from the inferior portion of the pancreas head that extends medially to the left, posterior to the superior mesenteric vessels. The head of the pancreas is attached to the medial aspect of the descending duodenum and its horizontal third portion, and the two organs share a blood supply. Posterior to the pancreatic head lie the inferior vena cava, right renal artery and vein, and left renal vein. In order for these structures to be exposed, the pancreas must be mobilized out the retroperitoneum (Kocher maneuver). The bile duct runs through the posterior and superior aspect of the pancreatic head, joining the pancreatic duct and draining into the duodenum medially at the ampulla of Vater.

The pancreatic neck is the 1.5 to 2.0 cm of pancreatic tissue that overlies the superior mesenteric artery and vein anteriorly. These vessels form a vascular groove in the posterior aspect of the gland. The anterior surface of the pancreatic neck is covered by peritoneum and lies directly posterior to the pylorus of the stomach. The splenic vein joins the superior mesenteric vein posterior to the pancreatic neck forming the portal vein, which drains the intestinal blood supply to the liver.

The body of the pancreas continues left from the pancreatic neck. The anterior surface of the pancreatic body is covered with peritoneum and forms the floor of the omental bursa within the lesser sac. The stomach overlies the pancreatic body/lesser sac anteriorly. The posterior surface of the pancreatic body is not peritonealized and directly contacts the aorta, left adrenal gland, left kidney, and left renal artery and vein. The body of the pancreas is the portion overlying the second lumbar vertebrae.

The tail of the pancreas begins anterior the left kidney and extends superolaterally to the hilum of the spleen. The splenic artery and vein run along the posterior surface of the pancreas. The tail of the pancreas is in close proximity to the spleen and splenic flexure of the colon.

Pancreatic Ductal Anatomy

The main pancreatic duct, or duct of Wirsung, begins in the pancreatic tail. It most commonly runs within the posterior aspect of the pancreatic parenchyma, midway between the superior and inferior border of the gland. In the head of the pancreas, the pancreatic duct turns inferiorly at the genu of the pancreatic duct and joins the common bile duct, draining into the duodenum at the ampulla of Vater 7 to 10 cm distal to the pylorus. The common channel between the common bile duct and main pancreatic duct varies in length. At the level of the ampulla of Vater, the pancreatic duct is anterior and inferior to the common bile duct. There are over 20 secondary branches of the main pancreatic duct throughout the pancreas providing drainage of acinar units.

The main pancreatic duct is 2 to 4 mm in diameter and has a ductal pressure of approximately 15 to 30 mm Hg. This is higher than the pressure in the common bile duct, 7 to 17 mm Hg, thereby preventing reflux of bile into the pancreatic ductal system. At the ampulla of Vater, the sphincter of Oddi prevents reflux of duodenal contents into the bile duct and pancreatic duct. This sphincter is controlled by a variety of neural and hormonal factors that regulate relaxation and constriction.

The accessory pancreatic duct, or duct of Santorini, is more variable than the main pancreatic duct (Fig. 51.3). It typically drains the uncinate process and inferior portion of the pancreatic head into the duodenum at the minor papilla, proximal to the ampulla of Vater.

Arterial Blood Supply

The pancreas has a rich blood supply derived from both the celiac axis and superior mesenteric artery. The celiac axis arises from the abdominal aorta and most commonly gives rise to the splenic artery, the left gastric artery, and the common hepatic artery (Fig. 51.7A). The splenic artery courses along the posterior surface of the pancreatic body and tail and gives rise to more than 10 branches that supply the pancreatic body and tail. Three of these branches are named branches. The first is the dorsal pancreatic artery, which arises close to the origin of the splenic artery and supplies blood to the proximal body. The great pancreatic artery arises more distally and supplies the midportion of the body. Finally, the caudal pancreatic artery arises more distally and supplies the pancreatic tail. Near the head of the pancreas, branches arising from the splenic artery form collaterals with the inferior pancreaticoduodenal arcades.

The gastroduodenal artery is the first branch off the common hepatic artery. Distal to the first portion of the duodenum, the gastroduodenal artery becomes the superior pancreaticoduodenal artery and divides into anterior and posterior branches.

The superior mesenteric artery gives rise to the inferior pancreaticoduodenal artery, which also gives rise to anterior and posterior branches. The inferior and superior pancreaticoduodenal arcades form an extensive collateral network with the superior pancreaticoduodenal arcades, supplying both the duodenum and head of the pancreas. Anteriorly, these arcades lie in the groove between the pancreas and duodenum. Posteriorly, they cross the common bile duct.

Variations or anomalies in the pancreatic and biliary blood supply are found in 20% to 30% of people and mainly consist of portions of the hepatic arterial blood supply being replaced. In these cases, all or part of the hepatic arterial blood supply does not arise from the celiac axis. As much of the pancreatic blood supply is derived from the hepatic arterial blood supply, these variations lead to variations in the pancreatic blood supply. The most common anomaly is a replaced right hepatic artery arising from the superior mesenteric artery (SMA; Fig. 51.7D). This variation is seen in approximately 20% of patients. The replaced right hepatic artery arises from the proximal SMA in the retropancreatic position and traverses the upper edge of the uncinate process, then runs posterolateral to the portal vein. The right hepatic artery can also originate from the right gastric artery in 2% of cases or from the gastroduodenal artery in 6% of cases.

Anomalies in the common hepatic artery also exist, with the most common being a common hepatic artery originating from the SMA instead of the celiac axis (Fig. 51.7C). In this case, there is no hepatic arterial pulse medially in the hepatoduodenal ligament. The replaced common hepatic artery runs anterior to the portal vein but posterior to the bile duct and gives rise to a gastroduodenal branch, which is also posterior to the bile duct. In approximately 10% of cases, the left hepatic artery can be aberrant, most commonly arising from the left gastric artery instead of the proper hepatic artery.

FIGURE 51.7. A: Arterial supply to the pancreas. B: Normal configuration. C: Aberrant common hepatic artery. D: Aberrant right hepatic artery. E: 1, Common hepatic artery looping around the portal vein from behind (causing compression of the vein); 2, aberrant left hepatic artery arising from the left gastric artery. (A, After Woodburne RT. *Essentials of Human Anatomy*. New York: Oxford University Press; 1973. B–E, After Trede M, Carter D Sir. *Embryology and Surgical Anatomy of the Pancreas*. New York: Churchill Livingstone; 1997.)

The arterial blood supply of the ampulla of Vater is from three pedicles off the superior and inferior pancreaticoduodenal arteries. The posterior pedicle, located at 11 o'clock, arises from the superior pancreaticoduodenal artery. The ventral commissural pedicle, located at 1 o'clock, arises from both arcades. Finally, the inferior pedicle, located at 6 o'clock, arises from the anterior branch of the inferior pancreaticoduodenal artery.

Venous Drainage

The venous drainage of the pancreas follows the arterial blood supply and is eventually returned to the portal circulation and delivered back to the liver. There are four main routes of

venous drainage in the pancreas. In the pancreatic head, superior venous arcades drain either directly into the suprapancreatic portal vein or laterally into the retropancreatic portal vein. The anterior and inferior branches of the pancreaticoduodenal arcades of the pancreatic head drain directly into the infrapancreatic superior mesenteric vein. There are rarely any anterior branches from the pancreatic head and neck into the superior mesenteric and portal veins. When they do occur, it is most commonly at the superior border of the pancreatic neck. The body and tail of the pancreas have many venous tributaries that drain into the splenic vein, which joins the superior mesenteric vein posterior to the pancreatic neck, forming the portal vein. The three named tributaries of the splenic vein are the inferior pancreatic vein, the caudal pancreatic vein, and the great

pancreatic vein. The inferior mesenteric vein does not drain the pancreas, but joins the splenic vein posterior the pancreatic body.

Lymphatic Drainage

Throughout the pancreas there is a rich periacinar network of lymphatic vessels that drain to five major nodal groups.¹⁹ The first is the superior nodal group along the superior border of the pancreas and celiac trunk. These lymph nodes drain the superior portion of the pancreatic head. The inferior nodal group along the inferior border of the head and body of the pancreas drains the inferior pancreatic head and uncinate process, eventually draining to the superior mesenteric and para-aortic lymph nodes. The anterior lymphatics drain to the prepyloric and infrapyloric nodes. The posterior lymph nodes include the distal common bile duct and ampullary lymphatics and drain directly into the para-aortic lymph nodes. Lastly, the splenic lymph nodes drain the lymphatics of the pancreatic body and tail into the interceliomesenteric lymph nodes.

The Japanese Pancreas Society has classified the pancreatic lymphatic drainage into 18 lymph node stations.²⁰ The greater and lesser curves of the stomach drain into lymph node stations 1 through 4. The anterior lymphatics described earlier drain into lymph node stations 5 and 6. The superior nodal group includes lymph node stations 7 through 9 along the left gastric

artery, common hepatic artery, and celiac axis. The splenic lymph node group corresponds to lymph node stations 10 and 11. The posterior lymph nodes include lymph node stations 12 (and all subdivisions) and 13, while the inferior nodal group includes lymph node stations 14 through 18. This classification system is commonly used to describe the extent of nodal dissection in pancreatic surgery.

Innervation

The innervation to the pancreas is derived from the vagus and thoracic splanchnic nerves as well as peptidergic neurons that secrete amines and peptides.²¹ Parasympathetic and sympathetic fibers reach the pancreas by passing along the arteries from the celiac axis and superior mesenteric arteries (Fig. 51.8). These fibers give rise to periacinar plexuses within the pancreatic parenchyma, which send fibers directly to the acinar cell group. The pancreatic islets and islet vasculature are similarly innervated. The parasympathetic nerves stimulate both exocrine and endocrine secretion, while the sympathetic fibers have a predominantly inhibitory effect (Fig. 51.9).²² The peptidergic neurons secrete hormones including somatostatin, vasoactive intestinal peptide (VIP), calcitonin gene-related peptide (CGRP), and galanin. While the peptidergic neurons influence exocrine and endocrine secretion, their precise physiologic role is unclear. The pancreas also has a rich network of afferent sensory fibers.

FIGURE 51.8. Diagram of the autonomic nerve supply to the pancreas. The innervation to the pancreas is derived from the vagus and thoracic splanchnic nerves. Parasympathetic and sympathetic fibers reach the pancreas by passing along the arteries from the celiac axis and superior mesenteric arteries. (After Skandalakis JE, Gray SW, Rowe JS Jr, et al. *Anatomical complications of pancreatic surgery*. *Contemp Surg* 1979;15:17.)

FIGURE 51.9. Schematic diagram of the neurohormonal control of the exocrine cells. Visceral receptors line the ductule system and carry the sensation of pain to the spinal cord. Sympathetic fibers first synapse in the celiac plexus after traveling through the thoracic ganglia and splanchnic nerves. Postganglionic fibers then synapse on intrapancreatic arterioles. Parasympathetic preganglionic fibers travel through the celiac plexus after leaving the vagus nerves and course with vessels and ducts to synapse on postganglionic fibers near acinar cells, islet cells, and smooth muscle cells of major ducts. Stimulation of these parasympathetic fibers results in an immediate release of pancreatic enzymes. Secretin and cholecystokinin (CCK) first enter the pancreas through the capillary network of the islet cells, then enter the separate capillary network of the acinar tissue through the insuloacinar portal vessels. Glucagon, somatostatin, pancreatic polypeptide, and insulin from the islet cells reach the acinar tissue immediately after release. In this way, the islet cells can influence the acinar tissue responses to CCK and secretin. (After Tompkins RK, Traverso LW. The exocrine cells. In: Keynes WM, Keith RG, eds. *The Pancreas*. New York: Appleton-Century-Crofts; 1981.)

SURGICAL SIGNIFICANCE OF PANCREATIC ANATOMY

The proximity of the pancreas to major visceral arteries, veins, and other abdominal organs makes the understanding of pancreatic anatomy critical for the general and pancreaticobiliary surgeon. Knowledge of the anatomy and anatomic variants can give clues to the diagnosis of pancreatic disease based on signs and symptoms and prevent injury to surrounding structures in the operating room.

Presenting Signs and Symptoms of Pancreatic Disease

Pancreatic cancer can occur anywhere in the pancreas, but it occurs in the pancreatic head in approximately 75% of cases.²³ Patients with cancer in the head of the pancreas often present with obstructive jaundice secondary to occlusion of the intrapancreatic bile duct. Patients with cancer in the body and tail of the pancreas often present with abdominal pain

and other vague abdominal symptoms as these tumors do not obstruct the bile duct and lead to obvious clinical signs. As a result, tumors in the pancreatic head are often picked up at an earlier stage. In fact, in resected series, nearly 85% of resected pancreatic tumors are in the head, neck, or uncinus process of the pancreas.²⁴ Similarly, in benign pancreatic diseases such as chronic pancreatitis, disease in the pancreatic head may cause benign biliary strictures and jaundice, whereas disease in the body and tail more often presents with abdominal pain.

Patients with cancer in the pancreatic head often have invasion of the adjacent duodenum. They may present with or develop signs and symptoms of duodenal or gastric outlet obstruction. In patients with unresectable disease, late gastric outlet obstruction occurs in 10% to 20% of patients requiring gastrojejunostomy. A prospective randomized trial demonstrated that the addition of prophylactic gastrojejunostomy to hepaticojejunostomy significantly reduced gastric outlet obstruction in patients with unresectable disease undergoing open biliary bypass.²⁵

Abdominal pain and back pain are common presenting symptoms in patients with acute pancreatitis, chronic pancreatitis, and pancreatic cancer. The rich afferent sensory fiber

network within the pancreas likely contributes to the pain associated with pancreatic disease processes including pancreatic cancer and chronic pancreatitis. In addition, as pancreatic cancer progresses, the nervous plexuses along the celiac axis in the retroperitoneum can be invaded by tumor, causing the characteristic intractable back pain. Celiac ganglion blockade (sympathectomy) or neurolysis using alcohol can provide significant pain relief by interrupting these somatic fibers. A celiac block can be performed endoscopically, percutaneously, or intraoperatively. Endoscopic ultrasound (EUS)- or CT-guided celiac plexus neurolysis should be considered first-line therapy in patients with pain secondary to unresectable, locally advanced pancreatic cancer.²⁶ In addition, intraoperative celiac blockade has been shown to reduce pain in patients with unresectable pancreatic cancer undergoing operative bypass procedures for obstructive jaundice and duodenal obstruction.²⁷ The use of celiac plexus blockade as routine therapy for pain in chronic pancreatitis is currently not recommended since only 50% of patients experience reduction in pain and the beneficial effect lasts only several months.²⁶

Resectability and Involvement of Adjacent Structures

- 9 Resectability of pancreatic cancers depends on two things: the presence or absence of distant metastases and the extent of local invasion. Liver or lung metastases from hematogenous spread, peritoneal carcinomatosis, or lymphatic involvement outside of the resection field such as around the celiac axis or root of the mesentery is considered unresectable.

Pancreatic cancers in the head, neck, or uncinate process often involve the intrapancreatic bile duct and/or duodenum given their close proximity. Assuming no distant metastases, pancreatic head cancers are resectable if they do not involve the major vascular structures. Involvement of the celiac axis or superior mesenteric artery precludes surgical resection. In addition, occlusion or circumferential involvement of the superior mesenteric–portal vein confluence is considered a contraindication to surgical resection by most surgeons. However, resection of the portal vein–superior mesenteric vein confluence and reconstruction has been advocated by some groups for select patients with locally advanced disease who are good surgical candidates.^{28–32} The results have been mixed, but most studies show that limited venous resection and reconstruction is safe and has similar 5-year survival when compared to patients not undergoing venous resection. However, a recent systematic review of 52 nonduplicated studies suggests that cure is unlikely in patients with major vascular involvement. Such patients had high rates of concurrent lymph node metastases and low 5-year survival rates following pancreatectomy with major venous resection.³³

Pancreatic head cancer may also involve adjacent organs including the hepatic flexure of the colon, the gallbladder, or the stomach. If there are no distant metastases, resection of these organs en bloc is indicated.

For cancers in the body and tail without distant metastasis, involvement of the splenic artery and/or vein does not preclude resection, as these vessels are normally taken during the operation. However, involvement of the celiac axis or superior mesenteric artery precludes resection. Involvement of adjacent organs including the left kidney, left adrenal, spleen, and left colon can be resected if involved with tumor and there is no distant disease.

Blood Supply

Knowledge of the normal pancreatic blood supply is critical in order to perform an adequate cancer operation. As the duodenum and head of the pancreas share a blood supply, it is necessary to remove these organs en bloc when performing an operation for carcinoma. While the duodenum can be preserved in

resections performed for benign disease (duodenum-preserving pancreatic head resection), this is not the case in patients with cancer. Likewise, for cancers in the body and tail of the pancreas, it is necessary to resect the spleen and its blood supply since it shares a blood supply with the tail of the pancreas. For benign diseases of the pancreatic tail, the spleen can be preserved.

Extent of Lymphatic Resection

There has been significant debate regarding the extent of lymph node dissection necessary in patients undergoing curative resection for pancreatic cancer. Knowledge of the lymph node station numbers used by the Japanese Pancreas Society is useful in understanding the difference between standard pancreaticoduodenal resection and “extended” or “radical” dissection involving a more extensive lymphadenectomy. The results of a randomized trial reported in 2005 showed no difference in survival with standard compared to radical resection.^{34,35} Table 51.2 shows the difference in the extent of lymphadenectomy between the standard and radical procedures. The standard procedure includes the bile duct (station 12b2) and cystic duct lymph nodes (station 12c), the posterior (station 13) and anterior (station 17) pancreaticoduodenal lymph nodes, the superior mesenteric vein nodes (station 14v), and the nodes on the right side of the superior mesenteric artery (station 14b). Radical resection adds a distal gastrectomy (stations 3, 4, 5, and 6) and a retroperitoneal dissection extending from the right renal hilum to the left lateral border of the aorta horizontally with samples of celiac nodes, and from the portal vein to below the third portion of the duodenum vertically (lymph node stations 16a1, 16b2, and 9).

Aberrant Vascular Anatomy

Awareness of the common anatomic variants in biliary and pancreatic arterial supply is necessary to prevent major vascular injury and damage to the hepatic blood supply during pancreatic resection. The gastroduodenal artery (GDA) is the largest named artery taken during pancreaticoduodenectomy. In the normal case, the GDA arises from the common hepatic artery (Fig. 51.7A), entering the head of the pancreas anterior and medial to the bile duct. In the case of a replaced right hepatic artery arising from the superior mesenteric artery, the GDA arises from this replaced vessel and enters the pancreas posterior to the bile duct. In addition, this replaced right hepatic artery courses to the liver lateral to the bile duct and can easily be injured during dissection of the pancreatic uncinate process off of the superior mesenteric vessels. This replaced vessel can often supply the entire right lobe of the liver, causing significant hepatic ischemia if injured. In the case of a replaced right hepatic artery, there will still be a pulse medially in the hepatoduodenal ligament from the left hepatic artery, but this will supply only the left lobe of the liver.

In the case of a replaced common hepatic artery, there will be no pulse medially in the hepatoduodenal ligament and the entire hepatic blood supply will be from the superior mesenteric artery. The replaced vessel will again be posterior and lateral to the bile duct and at risk of injury if not correctly identified. Given the closer proximity of the replaced vessels to the pancreatic head and uncinate process, these vessels may also be more prone to direct involvement by tumor. If injured or involved with tumor and resected, these often require reconstruction to restore adequate hepatic blood supply.

Blunt Pancreatic Injury

The pancreas lies deep in the retroperitoneum. The pancreatic body lies anterior to the second lumbar vertebra. In cases of

blunt abdominal trauma, specifically deceleration injury, the pancreatic body is crushed against the second vertebral body and can be transected at this point. In trauma patients with elevated amylase and lipase levels, the trauma surgeon should be aware of this possibility and obtain cross-sectional pancreatic imaging to rule out ductal disruption. In the case of complete ductal disruption, distal pancreatectomy or drainage of the pancreas into the intestine may be necessary.

PANCREATIC PHYSIOLOGY

Exocrine Function

The pancreas secretes 1.5 to 3 liters of a colorless, odorless, isosmotic, and alkaline solution daily containing over 20 enzymes and zymogens. The enzymes and zymogens play a major role in the digestive activity of the gastrointestinal tract.

The alkaline solution secreted by the pancreas ranges in pH from 7.6 to 9.0. It carries the proteolytic enzymes to the duodenum in their inactive state, where it then serves to neutralize gastric acid and provides an optimal milieu for the function of these enzymes. Pancreatic secretion is regulated via an intimate interaction of both hormonal and neural pathways.

Gastric acid is the primary stimulus for release of secretin, which then stimulates the secretion of pancreatic fluid rich in water, electrolytes, and bicarbonate. In response to the presence of long-chain fatty acids, some essential amino acids (methionine, valine, phenylalanine, and tryptophan), and gastric acid, the duodenum and jejunum release cholecystokinin (CCK). CCK then stimulates enzyme-rich secretion from the pancreas. The presence of bile salts in the intestine also stimulates pancreatic secretion, integrating the function of the pancreas, biliary tract, and small intestine. Vagal (parasympathetic) afferent and efferent pathways strongly affect pancreatic secretion. In fact, the secretion of enzyme-rich fluid is

largely dependent on the vagal stimulation, whereas fluid and electrolyte secretion are more dependent on the direct hormonal effects of secretin and CCK. Parasympathetic stimulation also causes the release of VIP, which also serves to stimulate secretin secretion.³⁶

Many neuropeptides also influence pancreatic secretion in an inhibitory fashion. These include somatostatin, pancreatic polypeptide, peptide YY, calcitonin gene-related peptides, neuropeptide Y, pancreastatin, enkephalin, glucagon, and galanin. While these neuropeptides are known to play a role in the regulation of pancreatic secretion, the mechanisms of action and the intricate interplay between the neuropeptides are not fully understood.³⁶

Bicarbonate Secretion

Bicarbonate is the most physiologically important ion secreted by the pancreas. Bicarbonate is formed from carbonic acid by the enzyme carbonic anhydrase. The secretion of water and electrolytes originates in the centroacinar and intercalated duct cells (Fig. 51.5). These cells secrete 20 mmol of bicarbonate per liter in the basal state and up to 150 mmol/L in the maximally stimulated state.³⁶ The bicarbonate secreted from the ductal cells is primarily derived from the plasma and not from intracellular metabolism. Chloride efflux through the cystic fibrosis transmembrane conductance regulator (CFTR) leads to depolarization and bicarbonate entry through the sodium bicarbonate cotransporter.³⁶ As a result, chloride secretion varies inversely with bicarbonate secretion, with the sum of these two anions balancing the sodium and potassium cations and remaining constant and equal to that of the plasma.

10 Both secretin and VIP stimulate bicarbonate secretion by increasing intracellular cyclic adenosine monophosphate, which acts on the CFTR.³⁶ Secretin is released from the duodenal mucosa in response to a duodenal lumen pH of less than 3.0 due to gastric acid. CCK is a weak direct stimulator of bicarbonate secretion, but it acts as a neuromodulator and potentiates the stimulatory effects of secretin. Gastrin and acetylcholine are also weak stimulators of bicarbonate secretion.³⁷ Bicarbonate secretion is inhibited by atropine (vagal stimulation) and can be reduced by 50% after truncal vagotomy.³⁸ Islet peptides including somatostatin, pancreatic polypeptide, glucagon, galanin, and pancreastatin are thought to inhibit exocrine secretion.

Enzyme Secretion

Pancreatic enzymes originate in the acinar cells, which are highly compartmentalized. Proteins are synthesized in the rough endoplasmic reticulum, processed in the Golgi apparatus, then targeted to the appropriate cell compartment (zymogen granules, lysosomes, etc.). The acinar cells secrete enzymes that fall into three major enzyme groups: amylolytic enzymes, lipolytic enzymes, and proteolytic enzymes. Amylolytic enzymes such as amylase hydrolyze starch to oligosaccharides and the disaccharide maltose. Lipolytic enzymes such as lipase, phospholipase A, and cholesterol esterase function work in conjunction with bile salts to digest fats and cholesterol. Proteolytic enzymes include endopeptidases (trypsin and chymotrypsin), which act on the internal peptide bonds of proteins and polypeptides, and exopeptidases (carboxypeptidases), which act on the free carboxy- and amino-terminal ends of proteins. The proteolytic enzymes are secreted as inactive precursors. Enterokinase cleaves the lysine-isoleucine bond in trypsinogen to create the active enzyme trypsin. Trypsin then activates the other proteolytic enzyme precursors.³⁶

The enzyme groups are not secreted in a fixed ratio. Dietary alterations and stimulation by specific nutrients can result in

changes in the relative amounts of each enzyme type. When enzyme secretion is absent or impaired, malabsorption or incomplete digestion occurs, leading to fat and protein loss through the gastrointestinal tract. This is seen in patients with acute and chronic pancreatitis (who have destruction of the exocrine pancreas) and in patients who have undergone surgical resection of all or part of the pancreas. These patients often present with weight loss and steatorrhea. These signs and symptoms can be corrected by oral replacement of pancreatic enzymes with meals.

The nervous system initiates pancreatic enzyme secretion. This involves extrinsic innervation by the vagus nerve and subsequent innervation by the intrapancreatic cholinergic fibers. The neurotransmitters, acetylcholine, and gastrin-releasing peptides activate calcium-dependent release of zymogen granules.³⁶ CCK is also a predominant regulator of enzyme secretion, doing so through activation of specific membrane-bound receptors and calcium-dependent second messenger pathways. Secretin and VIP weakly stimulate acinar cell secretion independently, but they potentiate the effect of CCK on acinar cells. Insulin is required locally and serves in a permissive role for secretin and CCK to promote exocrine secretion (Fig. 51.10).³⁶

Through the secretion of the three classes of enzymes, the pancreas regulates complete digestion of carbohydrates, fats,

FIGURE 51.10. Schematic diagram of the acinar cell, demonstrating receptors for exocrine secretagogues and their intracellular bases of action. Six distinct classes of receptors are known, with principal ligands shown. CCK, cholecystokinin; CGRP, calcitonin gene-related peptide; DAG, diacylglycerol; VIP, vasoactive intestinal peptide.

and proteins. Autodigestion of the pancreas by these proteolytic enzymes is prevented by packaging of proteases in an inactive precursor form and by the synthesis of protease inhibitors including pancreatic secretory trypsin inhibitor (PSTI), serine protease inhibitor kazal type 1 (SPINK1), and protease serine 1 (PRSS1). These enzymes are found in the acinar cell and loss of these protective mechanisms can lead to activation, autodigestion, and acute pancreatitis. Mutations in the SPINK1 and PRSS1 genes are known to cause one of the aggressive familial forms of chronic pancreatitis, leading to recurrent episodes of pancreatitis with associated exocrine and endocrine insufficiency.^{39,40}

Endocrine Function

Insulin Synthesis, Secretion, and Action. Insulin is a 56-amino-acid polypeptide with a molecular weight of 6 kD. It consists of two polypeptide chains (A and B) joined by two disulfide bridges. The amino acid sequence varies among species, but the location of the disulfide bridges are highly conserved and are critical for its biologic activity. Insulin is synthesized by the B cells within the islets of Langerhans. Insulin functions to promote glucose transport in all cells except B cells, hepatocytes, and central nervous system cells. Insulin inhibits glycogenolysis and fatty acid breakdown but stimulates protein synthesis. There is a significant secretory reserve of insulin within the pancreas. Destruction or removal of 80% of the pancreatic islet cell mass is necessary before endocrine dysfunction becomes clinically apparent in the form of type 1 (insulin-dependent) diabetes.⁴¹

In response to pancreatic B-cell stimulation, proinsulin (precursor peptide to insulin) is synthesized in the endoplasmic reticulum and transported to the Golgi. In the Golgi, the proinsulin is packaged into granules, where it is cleaved into insulin and the residual connecting peptide, C peptide (Fig. 51.11). The granules are then released directly into the intervascular space. Defects in the synthesis and cleavage of insulin can lead to rare forms of diabetes mellitus such as Wakayama syndrome and proinsulin syndrome.⁴²

The secretion of insulin is tightly regulated by nutrient, neural, and hormonal factors. In response to glucose, the predominant nutrient regulator, insulin is secreted in two phases. The first phase is a short burst of stored insulin that lasts 4 to 6 minutes. This is followed by a sustained secretion of insulin, which requires active synthesis of the hormone within the islet cell. The B cell is sensitive to even small changes in glucose concentration and is maximally stimulated at concentrations of 400 to 500 mg/dL. Insulin is released in an oscillatory or pulsatile pattern controlled by an internal pacemaker, which is present even in isolated islet cells.⁴³ Insulin has a short half-life

of 7 to 10 minutes after secretion, when it is primarily metabolized by the liver. Forty percent to 70% of insulin secreted into the portal venous system is cleared by hepatocytes on the first pass through the liver. Excess insulin is then slowly metabolized by the liver, kidneys, and skeletal muscles. Both brain cells and red blood cells do not take up insulin.

Like all hormones, insulin binds to specific cell surface receptors that have been isolated and well characterized. The insulin receptor is a 300-kD glycoprotein. Stimulation of the insulin receptor is dependent on insulin concentration. Insulin resistance, present in type 2 diabetes, can be the result of decreased numbers of receptors or a decreased affinity for insulin.

Glucose is actively transported across cell membranes throughout the body by 55-kD membrane-bound facilitator peptides called glucose transporters (Fig. 51.12). There are several classes of glucose transporters with varying affinities for glucose. The GLUT-2 transporter located on B cells has a low affinity for glucose. This results in a low rate of transport at physiologic concentrations of glucose but an increased rate of transport at higher concentrations, with subsequent higher insulin secretion rates.⁴⁴ The loss of B-cell GLUT-2 transporter can contribute to the development of diabetes mellitus.⁴⁵

Orally administered glucose has a greater effect on insulin secretion than an equivalent amount of glucose administered intravenously. This effect is called the enteroinsular axis and is related to the release of enteric hormones in response to glucose that also potentiate insulin secretion. Gastric inhibitory polypeptide (GIP) is an important regulator of this effect.⁴⁶ Additional gut peptides and hormones that stimulate insulin secretion include glucagon, glucagonlike peptide-1, and CCK, while somatostatin, amylin, and pancreastatin inhibit insulin secretion. Nutrients including certain amino acids (arginine, lysine, and leucine) and free fatty acids also regulate insulin secretion. Sulfonylurea compounds, which act independently of glucose concentration, also stimulate insulin secretion and are used in the treatment of type 2 diabetes, where the primary defect is peripheral insulin resistance, not insulin production or decreased islet cell mass.

B cells are also neuronally regulated. Both cholinergic and b-sympathetic fibers stimulate insulin secretion, whereas a-sympathetic fibers are inhibitory. A loss of pancreatic innervation in the setting of pancreatic transplantation can therefore result in changes in the pattern and quality of insulin secretion.

Glucagon Synthesis, Secretion, and Action. Glucagon, secreted by the islet A, is a single-chain, 29-amino-acid polypeptide with a molecular weight of 3.5 kD. Glucagon elevates blood glucose levels through stimulation of glycogenolysis and gluconeogenesis in the hepatocytes. Like epinephrine, cortisol, and growth hormone, glucagon is considered a stress

FIGURE 51.11. Synthesis of insulin. Proinsulin is synthesized by the endoplasmic reticulum and packaged within the secretory granules of the B cell. There it is cleaved into insulin and C-peptide. Equimolar amounts of insulin and C-peptide are secreted into the bloodstream.

FIGURE 51.12. Model of the basic structure of a membrane-bound glucose transporter peptide, encoded by the gene divided into 10 exon regions. Membrane-spanning β -helical peptide chains are numbered M1 through M12. Mutations of the promoter region of the gene or the synthesis of an abnormal form of the protein could result in altered transport of glucose. For the B-cell GLUT-2 transporter, this could cause reduced sensitivity to glucose. For the muscle and fat cell GLUT-4 transporter, this could result in decreased peripheral uptake of glucose. (After Bell GI, Kayano T, Buse JB, et al. Molecular biology of mammalian glucose transporters. *Diabetes Care* 1990;86:1615.)

hormone because it increases metabolic fuel in the form of glucose during stress. Secretion of pancreatic glucagon is tightly controlled by neural, hormonal, and nutrient factors. Like insulin, glucose is the primary regulator, but the two hormones respond to glucose in reciprocal fashion. It has a strong suppressive effect on glucagon secretion. The two hormones are counterregulatory and function together to tightly control blood glucose levels. Excess glucagon can lead to hyperglycemia, whereas insufficient glucagon can lead to profound hypoglycemia. For this reason, the diabetes resulting from total pancreatectomy is very brittle and difficult to control due to the lack of endogenous glucagon to balance exogenously administered insulin.

Glucagon secretion is also stimulated by the amino acids arginine and alanine. Through paracrine effects within the islets, both insulin and somatostatin have a suppressive effect on glucagon secretion. The neural regulation of glucagon parallels that of insulin, with cholinergic fibers being strongly stimulatory, B-sympathetic fibers being weakly stimulatory, and A-sympathetic fibers being inhibitory.

Dysfunctional A-cell secretion of glucagon may play a role in the elevation of blood sugar in diabetes. Suppression of glucagon with somatostatin has been shown to improve glucose control in type 1 (insulin-dependent) diabetes.⁴⁷

Somatostatin Synthesis, Secretion, and Action.

- 11** Somatostatin is a 14-amino-acid polypeptide that inhibits the release of growth hormone. While endogenous somatostatin has not proven to directly influence the secretion of other peptide hormones from islet cells, exogenous administration of somatostatin has been shown to inhibit the release of insulin, glucagon, and pancreatic polypeptide (PP). It has also been shown to inhibit gastric, pancreatic, and biliary secretion.

A synthetic octapeptide that mimics somatostatin pharmacologically (Octreotide, Novartis, East Hanover, NJ) has been developed. It is a more potent inhibitor of growth hormone, glucagon, and insulin secretion than the natural hormone. The potent inhibitory effect of octreotide has been used to treat both exocrine and endocrine disorders of the pancreas. For example, in hormone-producing islet cell tumors that express somatostatin receptors, octreotide can effectively suppress the hormonal symptoms associated with the disease process.⁴⁸ Although still controversial due to mixed results, a recent meta-analysis has shown that prophylactic octreotide reduces pancreatic fistula formation following elective pancreatic surgery.⁴⁹ It has also been shown to decrease iatrogenic pancreatic fistula output once a fistula has developed.

Pancreatic Polypeptide Synthesis, Secretion, and Action.

PP is a 36-amino-acid polypeptide secreted by the F cells of the pancreatic islet. The physiologic role of PP remains unclear. It has been shown to inhibit pancreatic exocrine secretion and gallbladder emptying. Cholinergic innervation predominantly regulates PP secretion. As a result, surgical vagotomy ablates the increased PP response normally observed after meals. In diabetes and normal aging, PP secretion is increased, resulting in increased circulating PP levels.

Other Peptide Products

Other peptides are secreted within the pancreatic islet. These include neuropeptides such as VIP, galanin, and serotonin, which are believed to play a role in the regulation of islet cell secretion. Amylin, a 36-amino-acid polypeptide, is secreted by the B cells, but not in equimolar amounts to proinsulin. Amylin inhibits secretion of insulin and its uptake in the periphery. Amylin has been found to be deposited in the pancreas of patients with type 2 diabetes and has been implicated in the pathogenesis of the disease. Pancreastatin is another peptide found in large amounts in the pancreas. It is a derivative of chromogranin A, but its physiologic significance is unknown.

DIAGNOSTIC APPROACH TO PATIENTS WITH PANCREATIC DISEASE

Pancreatic Imaging (Studies of Pancreatic Structure)

If pancreatic disease is suspected, the pancreas can be imaged by several radiographic modalities including plain abdominal radiographs, upper gastrointestinal series, abdominal ultrasonography, CT, MRCP, endoscopic retrograde cholangiopancreatography (ERCP), and EUS.

Abdominal Plain Films

Plain films of the abdomen may be useful in patients with acute and chronic pancreatitis. In patients with acute pancreatitis, the most common findings on plain film include a generalized ileus with air–fluid levels, a localized ileus or “sentinel loop” of jejunum or duodenum in the area of the inflamed pancreas, or a cutoff of the colon due to distention of the transverse colon. In the setting of acute pancreatic fluid collections or pseudocysts, you can see an actual mass on plain film with displacement of the stomach or duodenum.⁵⁰ These findings are not sensitive or specific for acute pancreatitis, but in the setting of elevated amylase and lipase and associated abdominal symptoms, they can provide support for the diagnosis and an indication for more sensitive pancreatic imaging studies.

In the setting of chronic pancreatitis, the most common finding on plain film is the presence of calcifications within the pancreas. These are most commonly seen at the level of the second lumbar vertebra, where the pancreas lies in the retroperitoneum.

Upper Gastrointestinal Series

In the setting of a mass or mass effect on plain film, an upper gastrointestinal series can demonstrate displacement of the stomach or duodenum by a retroperitoneal mass. Displacement or narrowing of the duodenal C loop suggests the presence of a pancreatic mass. However, the character of the mass (inflammatory, neoplastic, cystic, etc.) cannot be further defined on upper gastrointestinal series.⁵⁰ For this reason, the upper gastrointestinal series has been largely replaced by ultrasound and other three-dimensional imaging modalities such as CT or MRCP.

Ultrasonography

Abdominal ultrasound can be useful in the setting of acute pancreatitis, chronic pancreatitis, pancreatic cystic lesions, pancreatic pseudocysts, and pancreatic cancer. In acute pancreatitis, the abdominal ultrasound may demonstrate gallstones, suggesting a potential etiology. In addition, the ultrasound can identify an enlarged pancreas, pancreatic edema, and peripancreatic fluid collections consistent with the diagnosis of acute pancreatitis. Ultrasound can also identify pancreatic pseudocysts, cystic lesions, and other pancreatic masses.⁵⁰ Pancreatic pseudocysts usually appear as a smooth, round fluid collection without acoustic shadowing. A pancreatic cancer is more likely to distort the underlying pancreatic anatomy and appear as a localized, solid lesion on ultrasound, also without acoustic shadowing. Cystic neoplasms of the pancreas can have both solid and cystic components. They can be uniloculated or multiloculated and contain cysts of varying size.

Ultrasound examination can be limited by obesity, overlying bowel gas, and recently performed barium contrast studies. Small masses or fluid collections can be easily missed. The presence of a mass on ultrasound is an indication for more extensive workup via CT or MRCP imaging.

Computed Tomography

Contrast-enhanced, helical three-dimensional CT is the most commonly performed study for the detection and characterization of pancreatic solid and cystic tumors. It is also useful in defining the pancreatic anatomy in the presence of chronic

pancreatitis and identifying and following the complications of acute pancreatitis. CT is very sensitive for identifying pancreatic masses as small as 1 cm and can accurately distinguish solid from cystic lesions. The density of the lesion on CT can provide clues as to the diagnosis. Pancreatic adenocarcinomas are usually solid and hypodense, whereas pancreatic neuroendocrine tumors are vascular and hyperdense. Both pseudocysts and cystic lesions have components with fluid density.

CT is sensitive for the diagnosis of a malignant pancreatic adenocarcinoma. However, it is less sensitive and accurate in the diagnosis of cystic lesions. As CT scans are more commonly performed for a variety of indications, many cystic lesions are found incidentally. CT can be useful in identifying the characteristics associated with malignancy including tumor size greater than 3 cm, a dilated main pancreatic duct, and mural nodules within the cystic lesion.⁵¹ However, a recent study showed that specific diagnosis was correct only 39% of the time based on CT findings alone and CT was only 61% accurate in making a benign versus malignant diagnosis.⁵²

Endoscopic Ultrasound

EUS provides higher-resolution images of the pancreatic parenchyma and pancreatic duct than transabdominal ultrasound. This procedure uses a transducer fixed to an endoscope that can be directed to the surface of the pancreas through the stomach or duodenum. Pancreatic masses and cystic lesions can be aspirated and/or biopsied via EUS, providing a useful adjunct to CT in the diagnosis of mucinous cystic lesions and malignancies. In addition, EUS can be used to perform celiac nerve blocks in the setting of intractable pain in unresectable pancreatic cancer.

EUS can provide cytologic information, information about pancreatic ductal anatomy, and information about invasion of major vascular structures. While more invasive than CT, it can provide useful additional information. In addition, it can provide information about pancreatic ductal anatomy without invasive pancreatography (ERCP), which can cause severe pancreatitis. As with any endoscopic procedure, the risks include perforation of the stomach and/or duodenum.

A list of 11 EUS criteria have been defined for the diagnosis of chronic pancreatitis. The ductal criteria include pancreatic duct stones, echogenic ductal walls, irregular ductal walls, pancreatic duct strictures, visible side branches, and ductal dilatation. The parenchyma criteria include echogenic strands, echogenic foci, calcifications, lobular contour, and pancreatic cysts. Recent studies have determined that three or more EUS criteria provide the best balance of sensitivity and specificity for histologic pancreatic fibrosis.⁵³

Magnetic Resonance Cholangiopancreatography

MRCP using three-dimensional turbo spin-echo techniques is now being used more commonly as a noninvasive way to image both the bile duct and pancreatic duct. This imaging modality can provide excellent images and detect abnormalities of the common bile duct and main pancreatic duct, but it is more limited in its ability to detect abnormalities in the secondary ducts. This noninvasive imaging technique is very useful in high-risk patients and pregnant patients. It is also useful in diagnosis, especially in settings where interventions such as biopsy or biliary drainage are unnecessary. MRCP can be a good modality for defining pancreatic ductal anatomy in patients with chronic pancreatitis and pancreatic pseudocysts to help plan operative management.

Endoscopic Retrograde Cholangiopancreatography

Like MRCP and EUS, ERCP can provide useful information about pancreatic ductal anatomy. Pancreatic cancer is characterized by obstruction or stenosis of the pancreatic duct and/or common bile duct (double duct sign). In chronic pancreatitis, the pancreatic duct may have irregularities including stenosis, dilation, sacculation, and ectasia. Pancreatic duct stones may be present within the pancreatic duct. Similar ductal changes can be observed immediately following acute attacks of pancreatitis.

As with any endoscopic procedure, perforation of the gastrointestinal tract is a potential complication of ERCP. Five to 20% of patients develop clinical pancreatitis after ERCP and 25% to 75% have elevated amylase and lipase levels.⁵⁰ There is no way to prevent post-ERCP pancreatitis; however, high-pressure injection of the pancreatic duct is thought to contribute. ERCP is performed less commonly since much of the information can now be obtained with CT and/or EUS. However, ERCP is still useful in the palliation of obstructive jaundice with endostent placement, neither of which can be achieved using the other modalities.

Tests of Pancreatic Exocrine Function

Several tests are useful in the assessment of pancreatic exocrine function. When pancreatic disease is suspected, the measurement of serum amylase and lipase levels serves as a useful screening test. As amylase is found in organs other than the pancreas (salivary glands, liver, small intestine, kidneys, fallopian tubes), serum amylase levels may be elevated in both pancreatic and nonpancreatic diseases (Table 51.3). Assays for

the isoenzymes of amylase can be performed but are unreliable in determining whether the source of amylase is pancreatic or nonpancreatic and are not widely used. It has been shown that serum lipase is a more accurate biomarker of acute pancreatitis than serum amylase, with 19% of patients with acute pancreatitis having normal serum amylase levels, but only 3% having normal serum lipase levels.⁵⁴ Unlike amylase and lipase, serum trypsinogen is made only by the pancreas and may serve as a better marker for acute pancreatitis. Trypsinogen can also be measured in the urine and serves as a specific screening test for acute pancreatitis.^{55,56} All three markers are cleared by the kidneys, so in the setting of acute renal failure, all may be falsely elevated.

In the case of acute pancreatitis, serum amylase and lipase levels are usually elevated and peak within 24 hours of the onset of symptoms and return to normal within 2 to 4 days if the inflammation resolves. In cases of severe necrotizing pancreatitis, pancreatic ductal obstruction, and pseudocyst formation, amylase and lipase levels can remain elevated for much longer periods of time. While amylase and lipase levels are elevated in over 85% of patients with acute pancreatitis, their elevation is far less common in chronic pancreatitis, where the exocrine function of the pancreas may be impaired. Amylase levels may be normal in patients with acute pancreatitis if there is a delay in their diagnosis or if their pancreatitis is related to hypertriglyceridemia, which can falsely decrease the serum amylase levels.⁵⁰

12 Several tests of pancreatic exocrine function require duodenal intubation: the secretin test, the dimethadione test (DMO), and the Lundh test. The classic test of pancreatic endocrine function is the secretin test.⁵⁷ A patient fasts overnight. A double-lumen tube is then placed in the duodenum. Basal collections are performed for 20 minutes and analyzed for total volume, bicarbonate output, and enzyme secretion. An intravenous bolus of 2 units of secretin per kilogram is given and four 20-minute collections are performed and analyzed as discussed earlier.

Normal values for the standard secretin stimulation test are 2.0 mL of pancreatic fluid per kilogram per hour, bicarbonate concentration of 80 mmol/L, bicarbonate output of greater than 10 mmol/L in 1 hour, and amylase secretion of 6 to 18 IU/kg. The maximal bicarbonate concentration provides the greatest discrimination between normal subjects and patients with chronic pancreatitis.⁵⁸ The results of the secretin stimulation test for different pancreatic disease processes is shown in Table 51.4.

The pancreas is known to metabolize the anticonvulsant drug trimethadione to its metabolite, DMO. To test pancreatic exocrine function, patients are given 0.45 g of trimethadione three times daily for 3 days. A double-lumen tube is placed in the duodenum and secretin is given to maximally stimulate pancreatic secretion. The duodenal output of DMO correlates well with exocrine function.⁵⁹

Likewise, a Lundh test requires duodenal intubation, but this test measures pancreatic enzyme secretion directly in response to a meal of carbohydrate, fat, and protein. A patient fasts overnight, then has a double-lumen duodenal tube placed. Basal duodenal fluid collection is performed and patients are then given a meal consisting of 18 g of corn oil, 15 g of casein, and 40 g of glucose in 300 mL of water. Duodenal fluid is collected every 30 minutes for 2 hours and analyzed for trypsin, amylase, and lipase. This test relies on endogenous secretin and CCK secretion and may be abnormal in diseases involving the intestinal mucosa.

The triolein breath test is a noninvasive test of exocrine insufficiency.⁶⁰ Twenty-five grams of ¹⁴C-labeled corn oil (triglycerides) is given to the patient orally. The metabolite, ¹⁴C carbon dioxide, can be measured in the breath 4 hours after administration. Patients with disorders of fat digestion or absorption exhale less than 3% of the dose per hour. The test can be repeated after pancreatic enzyme replacement. Patients

TABLE 51.3

PANCREATIC AND NONPANCREATIC CAUSES OF HYPERAMYLASEMIA

Pancreatic Diseases Causing Elevated Amylase Levels

Acute, uncomplicated pancreatitis
Pancreatic pseudocyst
Acute peripancreatic fluid collections
Pancreatic ascites
Pancreatic necrosis and/or abscess (infected pancreatic necrosis)
Pancreatic injury/trauma
Ductal obstruction in pancreatic cancer, pancreatic cystic neoplasms, or chronic pancreatitis

Nonpancreatic Diseases Causing Elevated Amylase Levels

Perforated duodenal ulcer
Duodenal ulcer penetrating pancreas
Small-bowel obstruction
Ruptured ectopic pregnancy
Peritonitis
Salivary gland lesions (mumps, salivary duct stones, sialadenitis, iatrogenic ductal obstruction)
Other cancers (lung, esophagus, breast, ovarian)
Burns
Diabetic ketoacidosis
Renal insufficiency
Pregnancy

TABLE 51.4

CHARACTERISTIC RESULTS OF SECRETIN TESTING: VOLUME, BICARBONATE CONCENTRATION, AND ENZYME SECRETION CHANGES IN PANCREATIC DISEASE PROCESSES

■ DISORDER	■ PATTERN	■ TOTAL VOLUME	■ MAXIMUM BICARBONATE SECRETION	■ ENZYME SECRETION
End-stage pancreatitis	Total insufficiency	Decreased	Decreased	Decreased
Advanced pancreatic cancer	Total insufficiency	Decreased	Decreased	Decreased
Chronic pancreatitis	Qualitative insufficiency	Normal	Decreased	Normal
Pancreatic cancer	Quantitative insufficiency	Decreased	Normal	Normal
Malnutrition ^a	Isolated enzyme deficiency	Normal	Normal	Decreased
Hemochromatosis, Zollinger-Ellison syndrome, cirrhosis	Hypersecretion	Increased	Normal	Normal

^aSprue, ulcerative colitis, and Crohn disease.

with pancreatic insufficiency will achieve a normal rate of excretion of ¹⁴C carbon dioxide, whereas patients with enteric disorders show no improvement.

N-benzoyl-1-tyrosyl-para-aminobenzoic acid (BT-PABA) is cleaved by chymotrypsin to form para-aminobenzoic acid (PABA), which is then excreted in the urine. The PABA test is performed by administering 1 g of BT-PABA in 300 mL of water orally. Urine is then collected for 6 hours. Patients with chronic pancreatitis excrete less than 60% of the ingested dose of PT-PABA.

Suspected pancreatic disease can also be confirmed giving patients a test meal and measuring serum levels of the islet cell hormone pancreatic polypeptide. Basal and meal-stimulated levels of serum PP are reduced in severe chronic pancreatitis and after extensive pancreatic resection. After an overnight fast, a test meal of 20% protein, 40% fat, and 40% carbohydrate is ingested. The normal basal range of PP is 100 to

250 pg/mL. In severe chronic pancreatitis, the basal levels are often less than 50 pg/mL. The normal response to a meal is a rise in PP levels to 700 to 1,000 pg/mL for 2 to 3 hours after the meal. In severe disease, this response is decreased to less than 250 pg/mL. PP release depends on intact pancreatic innervation and can also be decreased after truncal vagotomy or antrectomy or in the setting of diabetic autonomic neuropathy.

The fecal fat test measures intraluminal digestion products and is used to distinguish between pancreatic dysfunction and malabsorption due to enteric disease. Many tests can help differentiate the two types of steatorrhea (Table 51.5). Steatorrhea from pancreatic dysfunction is the result of lipase deficiency and is usually not present until lipase secretion is reduced by 90%. Fecal fat content is measured over a 24-hour time period. If the fecal fat is elevated to more than 20 g, this indicates pancreatic insufficiency, whereas steatorrhea in the presence of low levels of fecal fat (<20 g) indicates intestinal

TABLE 51.5

DIFFERENTIAL DIAGNOSIS OF INTESTINAL AND PANCREATIC STEATORRHEA

■ PARAMETER	■ INTESTINAL STEATORRHEA	■ PANCREATIC INSUFFICIENCY
24-hour fecal fat	<20 g; soapy consistency	>20 g; only seepage
D-xylose	Abnormal (low)	Normal
Secretin test	Normal	Abnormal
Small-bowel series	Abnormal	Normal
Small-bowel biopsy	Abnormal	Normal
PABA test	Normal	Abnormal
PP response to meal	Normal	Abnormal
Vitamin B ₁₂ and folate	Abnormal (low)	Normal
Treatment with pancreatic enzymes	No change	Improvement

PABA, para-aminobenzoic acid; PP, pancreatic polypeptide.

dysfunction. A reduction of fecal fat can be used to demonstrate adequate replacement of pancreatic enzymes in patients with endocrine insufficiency. However, this test is time consuming and disliked by patients, and pancreatic enzyme replacement is often titrated based on symptom relief once the diagnosis of pancreatic insufficiency is made.

Tests of Pancreatic Endocrine Function

The most widely used test of pancreatic endocrine function is the oral glucose tolerance test. This test, used to test for diabetes, measures the body's ability to utilize glucose. The oral glucose tolerance test provides an indirect assessment of the insulin response to an oral glucose load as it measures the glucose profile and not the actual insulin response. After an overnight fast, two basal blood samples are drawn and glucose levels are analyzed. Patients are then given an oral glucose load of 40 g/m² over 10 minutes. Blood samples are then drawn every 30 minutes for 2 hours. The fasting glucose level should be less than 110 mg/dL. Fasting levels between 110 and 126 mg/dL are considered borderline diabetes, and fasting levels above 126 mg/dL are diagnostic of diabetes. The 2-hour glucose level should be below 140 mg/dL. Two-hour levels between 140 and 200 mg/dL are borderline, and 2-hour levels over 200 mg/dL are again diagnostic of diabetes mellitus. The insulin response to oral glucose can be affected by enteric factors including hormones involved in the enteroinular axis (GIP, glucagonlike peptide-1, CCK). The test can also be affected by antecedent diet, drug use, exercise, and patient age.

The intravenous glucose tolerance test can be used to eliminate the gastrointestinal influences of glucose metabolism experienced in the oral test. This test measures the disappearance of plasma glucose after administration of an intravenous glucose bolus, which indirectly reflects both the secretion and action of insulin. This test is performed in similar fashion to the oral glucose tolerance test, except the glucose load is delivered as an intravenous bolus of 0.5 g/kg over 2 to 5 minutes. Blood is then drawn every 10 minutes for an hour. The disappearance of glucose per minute (K value) is calculated. A K value of 1.5 or higher is normal. The response to this test decreases with age, so the results should be age adjusted.

The intravenous arginine test and tolbutamide response test are used to help in diagnosis of hormone-secreting tumors. Arginine is known to stimulate the secretion of islet cell hormones. After an overnight fast, a patient is given a 30-minute intravenous infusion of 0.5 g/kg of arginine. Blood samples are taken every 10 minutes and radioimmunoassay are performed for the hormone in question. This test is most useful for glucagon-secreting tumors. Elevations of plasma glucagon levels to over 400 pg/mL are diagnostic for glucagonoma.

Tolbutamide is a sulfonylurea that stimulates insulin secretion. After the patient fasts overnight, blood samples are drawn and the patient is given 1 g of tolbutamide intravenously. Blood glucose is monitored for 1 hour and blood samples are drawn to determine levels of the hormone of interest. Sustained hypoglycemia with hypersecretion of insulin is diagnostic of insulinoma. Somatostatin levels more than twice as high as the normal values of the particular assay used are considered diagnostic of somatostatinoma.

In making the diagnosis of insulinoma, surreptitious exogenous administration of insulin must be ruled out. Both insulin and C-peptide levels can be measured in the bloodstream and should be present in a 1:1 ratio. Surreptitious administration of exogenous insulin can be differentiated from insulinoma by the absence of C-peptide in the case of the exogenously administered insulin. The "gold standard" for diagnosis of insulinoma is the 72-hour monitored fast. This test attempts to document the Whipple triad of hypoglycemia, neuroglycopenic symptoms concurrent with hypoglycemia, and resolution of

symptoms with administration of glucose. Patients are fasted in a monitored setting. All nonessential medications are stopped and patients can only drink water; black, decaffeinated coffee; and diet sodas. Glucose and insulin levels are closely monitored. The criteria for discontinuing the fast include serum glucose levels less than 45 mg/dL, and the patient must be symptomatic. The 72-hour fast is highly sensitive for insulinoma and a patient rarely finishes this test without an unequivocal diagnosis.

CHAPTER 52 ■ ACUTE PANCREATITIS

JASON S. GOLD AND EDWARD E. WHANG

KEY POINTS

- 1 In the United States, more than 75% of cases of acute pancreatitis are attributable to either gallstones or alcohol.
- 2 Approximately 80% of cases of acute pancreatitis are mild, are associated with minimal systemic derangements, and generally resolve within 5 to 7 days, even with minimal therapy.
- 3 Severe acute pancreatitis accounts for about 20% of cases and is defined as acute pancreatitis associated with one or more of the following: pancreatic necrosis, distant organ failure, and the development of local complications such as hemorrhage, abscess, or pseudocyst.
- 4 The mortality rate associated with severe acute pancreatitis ranges from 10% to 20%, with half of the deaths in the first 2 weeks as the result of systemic inflammatory response syndrome-induced multisystem organ failure and the remaining occurring later as the result of pancreatic necrosis/infection.
- 5 Computed tomography scanning is the most important imaging test for acute pancreatitis and is useful in confirming the diagnosis, assessing disease severity, and detecting complications.
- 6 The most important component of initial management of acute pancreatitis is fluid resuscitation.
- 7 Early endoscopic retrograde cholangiopancreatography with sphincterotomy and stone extraction has been shown in randomized controlled trials to benefit the subset of patients with gallstone pancreatitis who have associated obstructive jaundice and/or cholangitis.
- 8 Infection of pancreatic and peripancreatic necrosis complicates 30% to 70% of cases of acute necrotizing pancreatitis and most commonly becomes established during the second to third weeks after onset of disease.
- 9 Infected pancreatic necrosis can be diagnosed by fine-needle aspiration and is most effectively treated with mechanical débridement.
- 10 Treatment options for pancreatic pseudocysts include percutaneous aspiration, percutaneous drainage, internal drainage (performed surgically or endoscopically), or resection; surgical therapy is the best validated procedure and is associated with high efficacy and a low recurrence rate.

TABLE 52.1 CLASSIFICATION**TERMS USED IN THE CLASSIFICATION OF ACUTE PANCREATITIS**

■ TERM	■ DEFINITION
Mild acute pancreatitis	Acute inflammation of the pancreas with minimal distant organ dysfunction and an uneventful recovery
Severe acute pancreatitis	Acute pancreatitis associated with pancreatic necrosis, distant organ failure, and/or the development of local complications, such as hemorrhage, abscess, or pseudocyst
Acute fluid collections	Fluid collections that occur early in the course of acute pancreatitis, are located in or near the pancreas, and lack a wall of granulation or fibrous tissue
Pancreatic necrosis	Diffuse or focal areas of nonviable pancreatic parenchyma, typically associated with peripancreatic fat necrosis
Pseudocyst	Collection of pancreatic secretions enclosed by a wall of fibrous or granulation tissue arising as a consequence of acute pancreatitis, chronic pancreatitis, or trauma to the pancreas
Pancreatic abscess	Collection of pus, usually near the pancreas, containing little or no pancreatic necrosis; arises as a consequence of acute pancreatitis or trauma to the pancreas

Acute pancreatitis is an acute inflammatory process of the pancreas with variable involvement of other regional tissues or remote organ systems.¹ In the United States, more than 200,000 patients are hospitalized annually with acute pancreatitis as the primary diagnosis.² It is the principal cause of approximately 3,200 deaths per year and a contributing factor in an additional 4,000 deaths. The direct cost attributable to acute pancreatitis exceeds \$2 billion per year in the United States.

CLASSIFICATION AND DEFINITIONS

A useful and widely accepted system for defining and classifying the severity and complications of acute pancreatitis was

developed during a multidisciplinary symposium held in 1992.¹ The clinically based definitions reached by consensus are shown in Table 52.1. Efforts to refine this classification system are currently under way.³

PATHOLOGY AND PATHOPHYSIOLOGY

The typical pathologic correlate of mild acute pancreatitis is *interstitial (edematous) pancreatitis*, in which the pancreatic parenchyma is edematous and infiltrated with inflammatory cells. Gross architectural features are preserved. In contrast, severe acute pancreatitis (SAP) can be associated with *necrotizing pancreatitis*, in which variable amounts of pancreatic parenchyma and peripancreatic fat have undergone tissue necrosis, with vascular inflammation and thrombosis being prominent features.

Studies using experimental models suggest that prototypical molecular and cellular derangements lead to pancreatic injury, regardless of the specific etiology or inciting event that triggers an episode of acute pancreatitis. Among the earliest of these derangements appears to be abnormal activation of proteolytic enzymes within pancreatic acinar cells.⁴ Under normal conditions, trypsinogen and other digestive zymogens are stored in granules that are segregated from lysosomal enzymes (e.g., cathepsin B) and acid. Early in the course of acute pancreatitis, cytoplasmic vacuoles containing activated proteolytic enzymes appear. How the digestive enzymes are activated, and what role these vacuoles play, has been the subject of much investigation. In the prevailing model, trypsinogen is believed to be activated to yield trypsin either by colocalization with the lysosomal hydrolase cathepsin B⁵ or through autoactivation due to a moderately acidic pH.⁶ Recently, it has been noted that the cytoplasmic vacuoles appearing in the acinar cell in experimental acute pancreatitis share expression of proteins with autophagosomes. Autophagosomes are vacuoles that degrade cellular components such as organelles in the process of autophagy. Highlighting the possible importance of autophagy in the development of pancreatitis, mice lacking expression of the autophagy-related gene *Atg5* in the pancreas fail to exhibit prototypical features of acute pancreatitis.⁷

Acinar cell injury induced by active trypsin allows it to be released into the pancreatic parenchyma (Fig. 52.1), where it activates more trypsin and other digestive enzymes (e.g., chymotrypsin, phospholipase, and elastase). Trypsin can also activate the complement, kallikrein-kinin, coagulation, and fibrinolysis cascades within the pancreatic parenchyma. Activation of these enzymes is believed to initiate a vicious cycle in which

FIGURE 52.1. Schematic diagram depicting activation of proteolytic enzymes, possibly through colocalization of zymogen granules and lysosomes, and subsequent rupture of zymogen granules releasing the activated enzymes into the cytoplasm of the pancreatic acinar cell. The activated enzymes then undergo disordered basolateral discharge from the acinar cell into the pancreatic parenchyma.

activated enzymes cause cellular injury, an event that leads to the release of even more destructive enzymes. This cycle can overwhelm defense mechanisms that normally serve to limit the injurious consequences of premature trypsin activation within the pancreas (e.g., pancreatic secretory trypsin inhibitor-mediated inhibition of trypsin activity).

As injury progresses, the pancreatic parenchyma becomes infiltrated with macrophages and polymorphonuclear leukocytes, resulting in the release of a broad range of proinflammatory mediators (e.g., tumor necrosis factor; interleukins 1, 6, and 8; prostaglandins; platelet-activating factor; leukotrienes; and reactive oxygen species). The result of these events is pancreatic autodigestion, with injury to the vascular endothelium, interstitium, and acinar cells. Increases in vascular permeability lead to interstitial edema. Vasoconstriction, thrombosis, and capillary stasis can lead to ischemic (and perhaps ischemia-reperfusion injury) and the development of pancreatic necrosis. With severe pancreatic injury, the systemic inflammatory response syndrome (SIRS) and distant organ failure can occur. The systemic complications are believed to be mediated by digestive enzymes and inflammatory mediators released from the injured pancreas. For example, activated phospholipase A-induced digestion of lecithin (an important component of pulmonary surfactant) may play a role in the pathogenesis of acute respiratory distress syndrome (ARDS) that occurs in the setting of acute pancreatitis. In addition, the circulatory and inflammatory effects induced by acute pancreatitis are postulated to impair intestinal epithelial barrier function, allowing for the translocation of bacteria from the intestinal lumen into the systemic circulation. This phenomenon has been demonstrated to occur in animal models and may account for the pathogenesis of pancreatic and peripancreatic infection that can complicate necrotizing pancreatitis.

FIGURE 52.2. Illustration of the common channel concept. A gallstone lodged at the ampulla of Vater can cause reflux of bile into the pancreatic duct.

ETIOLOGY

- Although many etiologies of acute pancreatitis have been described, in the United States, more than 75% of cases are attributable to either gallstones or alcohol.

Gallstones

Gallstones cause approximately 35% of episodes of acute pancreatitis in the United States. In a mechanistic model proposed over a century ago, a gallstone lodged at the papilla of Vater occludes the ampullary orifice, leading to retrograde reflux of bile into the pancreatic duct through a common channel shared by the common bile duct and the pancreatic duct (Fig. 52.2). Although elements of this model have been challenged, the prevailing view is that transient or persistent obstruction of the ampullary orifice by a gallstone or edema induced by stone passage is the inciting factor in the pathogenesis of gallstone-induced pancreatitis. *Microolithiasis* refers to aggregates (<5 mm in diameter) of cholesterol monohydrate crystals or calcium bilirubinate granules detected as “sludge” within the gallbladder on ultrasonography or on examination of bile obtained during endoscopic retrograde cholangiopancreatography (ERCP). An etiologic role for microlithiasis in acute pancreatitis remains unproved; however, data derived from case-control studies suggest that cholecystectomy or endoscopic sphincterotomy can reduce the risk of recurrent acute pancreatitis in patients with microlithiasis.

Alcohol

Ethanol causes approximately 40% of cases of acute pancreatitis in the United States. Most patients with alcohol-induced acute pancreatitis also have underlying chronic pancreatitis. Potential mechanisms by which alcohol induces pancreatitis include sphincter of Oddi spasm, obstruction of small pancreatic ductules by proteinaceous plugs, alcohol-induced metabolic abnormalities (e.g., hyperlipidemia), and direct toxic effects induced by alcohol and its metabolites (e.g., acetaldehyde, acetate, and nonesterified fatty acids).

Other Etiologies

A wide range of other etiologies of acute pancreatitis have been identified (Table 52.2). Ongoing investigations are beginning to reveal specific gene abnormalities (e.g., mutations in cationic trypsinogen *PRSS1*, pancreatic secretory trypsin inhibitor *SPINK1*, and the cystic fibrosis transmembrane conductance regulator *CFTR*) that can be associated with pancreatitis. Patients for whom no etiology can be identified despite thorough evaluation are classified as having *idiopathic pancreatitis*.

CLINICAL PRESENTATION

Abdominal pain, nausea, and vomiting are the most prevalent symptoms associated with acute pancreatitis. The pain is visceral in quality, is localized to the epigastrium, often radiates to the back, and may be alleviated with the patient leaning forward. Abdominal tenderness is the most prevalent sign of acute pancreatitis. Tachycardia and hypotension may result from intravascular hypovolemia. Low-grade fevers are common, but high-grade fevers are unusual in the absence of intra- or extra-pancreatic infection. Jaundice may be evident in the presence of cholangitis (e.g., with gallstone-induced pancreatitis and persistent choledocholithiasis) or liver disease (alcohol-induced

pancreatitis in a patient with cirrhosis). Evidence of retroperitoneal hemorrhage may become apparent if blood dissects into the subcutaneous tissues of the flanks (Grey-Turner sign), umbilicus (Cullen sign), or inguinal region (Fox sign); however, these findings are unusual.

2 Approximately 80% of cases of acute pancreatitis are mild, are associated with minimal systemic derangements, and generally resolve within 5 to 7 days, even with minimal therapy. The mortality rate associated with mild acute pancreatitis is less than 1%.

3 Approximately 20% of cases are classified as *severe acute pancreatitis* (SAP), defined as acute pancreatitis associated with one or more of the following: (a) necrosis of greater than one third of the pancreas; (b) distant organ failure (indicated by systolic blood pressure ≤ 90 mm Hg, serum creatinine >2.9 mg/dL, gastrointestinal blood loss exceeding 500 mL in volume within a 24-hour period, and/or partial pressure of arterial oxygen [PaO_2] ≤ 60 mm Hg); and/or (c) the development of local complications, such as hemorrhage, abscess, or pseudo-

4 cyst.¹ The mortality rate associated with SAP ranges from 10% to 20% in contemporary series.^{8,9} One half of deaths occur within the first 2 weeks after the onset of symptoms; these deaths are primarily the result of SIRS-induced multisystem organ failure. Most of the remaining deaths occur 2 to 3 weeks after presentation and result from complications of pancreatic necrosis, especially infection.

DIAGNOSIS

The differential diagnosis of acute pancreatitis includes other conditions causing acute upper abdominal pain, such as biliary colic and cholecystitis, acute mesenteric ischemia, small-bowel obstruction, visceral perforation, and ruptured aortic aneurysm. Acute exacerbations of chronic pancreatitis can also be associated with clinical features resembling those of acute pancreatitis. The diagnosis of acute pancreatitis usually can be made by confirming biochemical evidence of pancreatic injury. Imaging tests should be used selectively to rule out other diagnoses and for the indications discussed later.

Laboratory Tests

With pancreatic injury, a variety of digestive enzymes escape from acinar cells and enter the systemic circulation. Of these enzymes, amylase is the most widely assayed to confirm the diagnosis of acute pancreatitis. Amylase levels rise within several hours after onset of symptoms and typically remain elevated for 3 to 5 days during uncomplicated episodes of mild acute pancreatitis. Because of the short serum half-life of amylase (10 hours), levels can normalize as soon as 24 hours after disease onset. The sensitivity of this test depends on what threshold value is used to define a positive result (90% sensitivity with a threshold value just above the normal range vs. 60% sensitivity with a threshold value at three times the upper limit of normal). Specificity (which also varies with the threshold values selected) is limited because a wide range of disorders can cause elevations in serum amylase concentration. Assays that detect increases in the serum concentration of amylase of pancreatic origin (P-isoamylase) alone are associated with greater specificity. Increased urinary amylase concentrations and amylase-to-creatinine clearance ratios occur with acute pancreatitis; however, these parameters offer no advantage over serum amylase concentrations, except in the evaluation of macroamylasemia (in which urinary amylase excretion is not increased despite elevations in serum amylase concentration).

Serum lipase concentrations increase with kinetics similar to those of amylase. It has a longer serum half-life than amylase, however, and may be useful for diagnosing acute pancreatitis late in the course of an episode (at which time serum amylase concentrations may have already normalized). Although lipase is more specific than amylase in the diagnosis of acute pancreatitis, note that lipase is produced at a range of nonpancreatic sites, including the intestine, liver, biliary tract, stomach, and tongue.

The magnitude of the increases in amylase or lipase concentrations has no correlation with severity of pancreatitis. In general, the magnitude of increases in amylase concentrations tends to be greater in patients with gallstone pancreatitis than in those with alcohol-induced pancreatitis; however, this finding is unreliable in distinguishing between these two etiologies.

Imaging Tests

Findings on plain radiographs associated with acute pancreatitis are nonspecific and include ileus that may be generalized or localized to a segment of small intestine ("sentinel loop") or transverse colon ("colon cut-off sign"), psoas muscle margins that are obscured by retroperitoneal edema, an

FIGURE 52.3. Computed tomography scan of acute interstitial pancreatitis.

elevated hemidiaphragm, pleural effusions, and basilar atelectasis.

Ultrasonography may reveal a diffusely enlarged, hypoechoic pancreas. However, overlying bowel gas (particularly prominent with ileus) limits visualization of the pancreas in a large percentage of cases. Although ultrasonography has poor sensitivity in the diagnosis of acute pancreatitis, it plays an important role in the identification of the etiology of pancreatitis (e.g., the detection of gallstones).

5 Computed tomography (CT) scanning is the most important imaging test in the evaluation of acute pancreatitis. CT findings of mild acute pancreatitis include pancreatic enlargement and edema, effacement of the normal lobulated contour of the pancreas, and stranding of peripancreatic fat (Fig. 52.3). In addition, dynamic CT scanning performed after the bolus administration of intravenous contrast can demonstrate regions of pancreas that have poor or no perfusion, as seen with pancreatic necrosis (Fig. 52.4). Detection of necrosis plays an important role in assessment of disease severity, as discussed further later.

Magnetic resonance imaging (MRI) and magnetic resonance cholangiopancreatography (MRCP) are being used with increasing frequency in patients with acute pancreatitis. These examinations have the potential to offer better definition of pancreatic and biliary ductal abnormalities than CT scanning, and they are applicable in patients for whom ionizing radiation or iodinated intravenous contrast agents used in CT scanning are contraindicated. Disadvantages of MRI include high cost, limited availability, and the long duration of examinations.

ASSESSMENT OF DISEASE SEVERITY

Accurate prediction of severity early in the course of disease offers potential benefits in that complications can be anticipated and detected early through the use of intensive monitoring and frequent clinical assessment, and early and aggressive therapies can be instituted to attempt to prevent these complications. Routine clinical assessment at the time of admission is associated with low sensitivities (<50%) in identifying patients with SAP.¹⁰ Therefore, alternative methods for assessing disease severity based on scoring systems, CT scanning, and serum markers have been widely studied. In addition to these meth-

FIGURE 52.4. Computed tomography scan of acute necrotizing pancreatitis.

ods, hemoconcentration and obesity have been reported to be predictive of severe disease.¹¹

Scoring Systems

The Ranson criteria (Table 52.3) are easily tabulated, and the resulting scores are well correlated with morbidity and mortality rates.¹² The presence of three or more of these criteria is indicative of SAP. Important limitations of the Ranson criteria are that the predictive score cannot be determined prior to 48 hours following admission and that it can only be used once. Furthermore, because these criteria were developed using a cohort of patients for whom alcohol was the predominant etiology of pancreatitis, their generalizability may be limited. A similar predictive scoring system developed in Glasgow using a cohort of patients for whom gallstones were the predominant etiology of pancreatitis is available.¹³

TABLE 52.3

STAGING

RANSON CRITERIA FOR ASSESSING SEVERITY OF PANCREATITIS

AT ADMISSION

Age	>55 y
WBC count	>16,000/mm ³
Glucose	>200 mg/dL
LDH	>350 IU/L
AST	>250 IU/L

WITHIN 48 H

Hematocrit decrease	>10 pt
BUN increase	>5 mg/dL
Calcium	<8 mg/dL
PaO ₂	<60 mm Hg
Base deficit	>4 mEq/L
Fluid requirement	>6 L

AST, aspartate aminotransferase; BUN, blood urea nitrogen; LDH, lactate dehydrogenase; PaO₂, partial pressure of arterial oxygen; WBC, white blood cell.

Acute Physiology and Chronic Health Evaluation (APACHE) II scores, which are based on patient age, indices of chronic health, and physiologic parameters, can be determined at any time after admission, can be updated continuously during the course of disease, and may have greater predictive power than Ranson scores.¹⁴ However, the complexity of calculating APACHE II (or related APACHE III) scores limits its application in routine clinical practice.

Computed Tomography Scanning

The diagnostic application of CT scanning was discussed previously. For assessment of disease severity, dynamic intravenous contrast-enhanced CT scanning should be obtained. This technique is associated with greater than 90% sensitivity in the detection of pancreatic necrosis, a finding that is predictive of severe disease, and is indicated if clinical deterioration occurs or if one of the scoring systems discussed earlier suggests severe disease (e.g., presence of three or more Ranson criteria or APACHE II score ≥ 8). Because necrosis takes time to develop, a contrast-enhanced CT scan obtained too early in the disease course (e.g., at the time of admission) is unlikely to have predictive value. In addition, concerns that early administration of iodinated intravenous contrast agents used in CT scanning may exacerbate pancreatic injury have been raised, although these agents have not been shown to cause or exacerbate pancreatitis in humans.¹⁵

Serum and Urinary Markers

C-reactive protein (CRP) is an easily assayed marker for which serum concentrations are well correlated with disease severity. However, CRP levels do not become significantly elevated until 48 hours after onset of disease; therefore, this marker is not useful for early prediction of disease severity. Serum concentrations of neutrophil elastase and interleukin 6 and urinary concentrations of TAP (a product of trypsinogen activation) are also correlated with disease severity. Because these markers become elevated within 24 hours of disease onset, they may be relevant to early prediction strategies in the future. Currently, however, assays for these markers are not widely available.

MANAGEMENT

The goals of management for patients with acute pancreatitis are summarized next.

Correcting Pathophysiologic Derangements and Ameliorating Symptoms

- 6 The most important component of initial management is fluid resuscitation. Third-space fluid losses can be large, with up to one third of plasma volume being sequestered. An indwelling urinary catheter should be placed, intravascular volume should be frequently assessed, and aggressive fluid and electrolyte replacement should be ensured.

Patients with SAP, as well as those for whom initial resuscitation fails, are best managed in a dedicated intensive care unit (ICU). Central venous monitoring may facilitate fluid management. Patients should be closely monitored for development of distant organ failure, particularly respiratory, cardiovascular, and renal failure, so that supportive management of these conditions (positive-pressure ventilation, administration of vasopressor agents, and hemodialysis, respectively) can be instituted without delay.

Abdominal pain is usually ameliorated with intravenous narcotics. In the past, morphine was avoided because of con-

cerns that morphine-induced increases in sphincter of Oddi pressure might exacerbate an episode of pancreatitis. However, there is no clinical evidence that morphine can induce or exacerbate acute pancreatitis. Other analgesic agents commonly used in patients with acute pancreatitis include meperidine and fentanyl. Evacuation of gastric contents using a nasogastric tube should be instituted if vomiting is a prominent symptom; otherwise, it is unnecessary.

Minimizing Progression of Pancreatic Inflammation and Injury

Identification of strategies for interrupting the inflammatory cascades that induce pancreatic injury and distant organ failure is an area of active investigation. Currently, the only method used in routine clinical practice is bowel rest (nothing by mouth). The rationale underlying this approach is that avoidance of bolus oral nutrient intake may limit stimulation of pancreatic exocrine secretion induced by the presence of nutrients in the intestine, particularly the duodenum.

Patients with mild acute pancreatitis generally need no nutritional support, as their disease typically resolves within 1 week. In contrast, patients with SAP usually have a more prolonged disease course and should begin to receive nutritional support as early as feasible. Although these patients traditionally have been administered total parenteral nutrition (TPN), accumulating evidence suggests that enteral nutrition is safe, is less costly, and may be associated with a lower complication rate than TPN.¹⁶ Administration of enteral nutrition is also associated with the theoretical advantage of helping to maintain the integrity of the intestinal mucosal barrier, thus potentially limiting or preventing bacterial translocation. Enteral nutrients have typically been delivered to the jejunum through nasojejunal tubes to avoid stimulating pancreatic exocrine secretion; however, randomized controlled trials indicate that continuous feedings delivered through nasogastric tubes are equally safe and effective.¹⁷ TPN is still required in many patients who do not tolerate enteral nutrition due to ileus.

Clinical trials of agents that inhibit activated pancreatic enzymes, inhibit pancreatic secretion, or interrupt the inflammatory cascade have yielded disappointing results. Meta-analyses of clinical trials of gabexate mesylate (a proteinase inhibitor), somatostatin, and octreotide suggest these agents have limited, if any, efficacy in improving outcomes in acute pancreatitis. A platelet-activating factor antagonist, lexipafant, showed promise in an initial study but not in a subsequent larger trial and is not currently recommended. Other adjuncts for which clinical trials have failed to demonstrate efficacy in limiting pancreatic injury in patients with acute pancreatitis include glucagon, anticholinergics, fresh frozen plasma, and peritoneal lavage.

Treating the Underlying Cause

This discussion is particularly relevant to patients with gallstone pancreatitis. There is both theoretical and experimental rationale to believe that removal of gallstones impacted at the ampulla of Vater early in the course of an episode of acute gallstone pancreatitis might limit disease severity. The efficacy of early ERCP to accomplish this goal has been subjected to prospective, randomized clinical trials.^{18,19} These studies show that early ERCP with stone extraction and sphincterotomy benefits the subset of patients with gallstone pancreatitis who have obstructive jaundice and/or cholangitis. In the absence of these features, early ERCP is associated with high complication rates but no apparent benefits and is therefore not recommended.

There is a 25% incidence of recurrent pancreatitis or other gallstone-related complications during the 6-week period following an episode of gallstone pancreatitis in patients who do not undergo cholecystectomy. Indeed, there is a substantial

incidence of recurrent pancreatitis and gallstone-related complications in patients with biliary pancreatitis whose cholecystectomy is delayed even 2 weeks after hospital discharge.²⁰ Therefore, cholecystectomy should be performed during the same hospitalization for most patients with mild gallstone pancreatitis. In severe biliary pancreatitis, the risk of deferring surgery needs to be balanced against the risk of performing early surgery in patients who are debilitated and nutritionally compromised. Endoscopic sphincterotomy is another option; however, the high risk of recurrent gallstone-related complications and the higher mortality compared to cholecystectomy suggest that this strategy should be reserved for patients with severe comorbidities precluding safe surgery.²¹

Examples of other measures directed at correcting the underlying cause of pancreatitis include cessation of drugs known to cause pancreatitis and treatment of hypercalcemia or hyperlipidemia.

Preventing and Treating Complications

Complications of acute pancreatitis include pancreatic abscesses and infected necrosis, acute fluid collections and pseudocysts, pancreatic ascites and fistulas, splenic vein thrombosis, and arterial pseudoaneurysms (Table 52.4). Infected necrosis and pseudocysts are discussed in detail next.

- 8 Infected Necrosis.** Infection of pancreatic and peripancreatic necrosis complicates 30% to 70% of cases of acute necrotizing pancreatitis and most commonly becomes established during the second to third weeks after onset of disease. Historical data suggest that mortality rates associated with untreated infected necrosis approach 100%. The diagnosis of infected necrosis is made based on cultures of aspirates of fluid or necrotic tissue obtained during CT-guided fine-needle aspiration (FNA) or specimens collected during surgery. The concordance rate between bacteriologic results of FNA and those of surgical specimens is greater than 95%.²² In addition, the visualization of air bubbles within necrotic tissue on CT scans is highly suggestive of infection. Because the presence or absence of infection has a strong impact on surgical decision making, FNA should be obtained in patients with acute necrotizing pancreatitis who exhibit clinical features of sepsis or whose clinical course deteriorates beyond 1 to 2 weeks after onset of disease.

If FNA indicates the presence of infected necrosis, surgical intervention is indicated. Infected necrosis consists of thick and tenacious material that is most effectively treated with mechanical débridement. Traditionally, the abdomen is entered through a vertical midline or bilateral subcostal incision. The anterior surface of the pancreas can be exposed by dividing the gastrocolic ligament (greater omentum) and entering the lesser sac. If inflammatory changes have obliterated the lesser sac, this approach may be hazardous. In such cases, an alternative route to the pan-

creas is achieved by dividing avascular portions of the transverse mesocolon, with care taken to preserve the middle colic vessels. Clearly nonviable tissue should be débrided bluntly. Anatomic resections should be avoided to minimize potential for removing viable pancreatic parenchyma. The débridement field is irrigated with several liters of sterile saline, after which large-bore drains are placed. Postoperatively, the drains are left in place at least 7 days and until the effluent becomes clear. If more prolonged drainage is necessary because a pancreatic fistula develops, the surgically placed drains should be replaced with soft, smaller-bore drains to minimize potential for bowel erosion.

The procedure described previously is known as *necrosectomy with closed drainage*. In a variant of this procedure, both gauze packing and drains are placed at the time of surgery and gradually withdrawn postoperatively. Other procedures include *necrosectomy with open packing* and *necrosectomy with planned, staged relaparotomy* in which the initial operation is followed by repeat laparotomies, during which gauze packing is changed or additional débridement is performed, every 2 days until all necrotic tissues have been removed. Another option is *necrosectomy with continuous lavage* in which high-volume lavage of the lesser sac is performed, using drains placed at the time of surgery, until the effluent becomes clear and the patient's clinical course improves. These latter procedures are resource intensive but may be necessary if necrosectomy is performed early in the course of disease, before clear demarcation between necrotic and viable tissues has occurred. Modern mortality rates associated with necrosectomy performed for infected necrosis range from 10% to 20%.^{8,9} On long-term follow-up, approximately 25% of survivors develop exocrine insufficiency, and 30% develop endocrine insufficiency.

Recently, less invasive approaches to necrosectomy have been reported. Percutaneous catheter drainage has been attempted. While this technique has become standard for pancreatic abscess, complete removal of all necrotic tissues often is difficult to achieve with drainage alone. A few centers have reported promising results using a video-assisted technique for mechanical débridement. This technique, called minimally invasive pancreatic necrosectomy, is usually accomplished through a retroperitoneal approach via flank incisions. Irrigation is usually continued postoperatively through surgically placed drains.²³ In a recently reported randomized controlled trial, patients with infected pancreatic necrosis were randomized to undergo primary open necrosectomy or a step-up approach consisting of percutaneous or endoscopic drainage followed, in most cases (65%), by *minimally invasive pancreatic necrosectomy*. Although mortality between the two groups did not differ, primary open necrosectomy was associated with a higher incidence of major complications.²⁴ Additional ongoing studies are evaluating the efficacy and safety of this and related approaches.

Although surgical débridement is clearly indicated for infected necrosis, its role in sterile necrosis has undergone evolution. In the past, early necrosectomy was recommended for patients with necrotizing pancreatitis, even in the absence of documented infection. The rationale for this approach was to prevent infection from developing and to remove the source of toxins and inflammatory mediators. Today, most authors recommend avoiding surgery in patients without documentation of infected necrosis, based on favorable outcomes reported using this conservative approach.^{8,9} However, there remains a subset of patients with sterile necrosis who, despite prolonged supportive care, have persistent problems, including pain, malaise, and gastric outlet obstruction. If necrosectomy is performed to provide symptomatic palliation, it should be delayed until at least 4 weeks after onset of disease, to maximize the probability of clear-cut demarcation between viable and nonviable tissues.

Because of the high morbidity and mortality rates associated with infected necrosis, there has been much investigation into the use of antibiotics as prophylaxis against infection.

TABLE 52.4 **COMPLICATIONS**

LOCAL COMPLICATIONS OF ACUTE PANCREATITIS

- Infected necrosis
- Acute fluid collections
- Pancreatic abscesses
- Pancreatic pseudocyst
- Pancreatic ascites
- Enteric or colonic fistula
- Splenic vein thrombosis
- Arterial pseudoaneurysm
- Hemorrhage

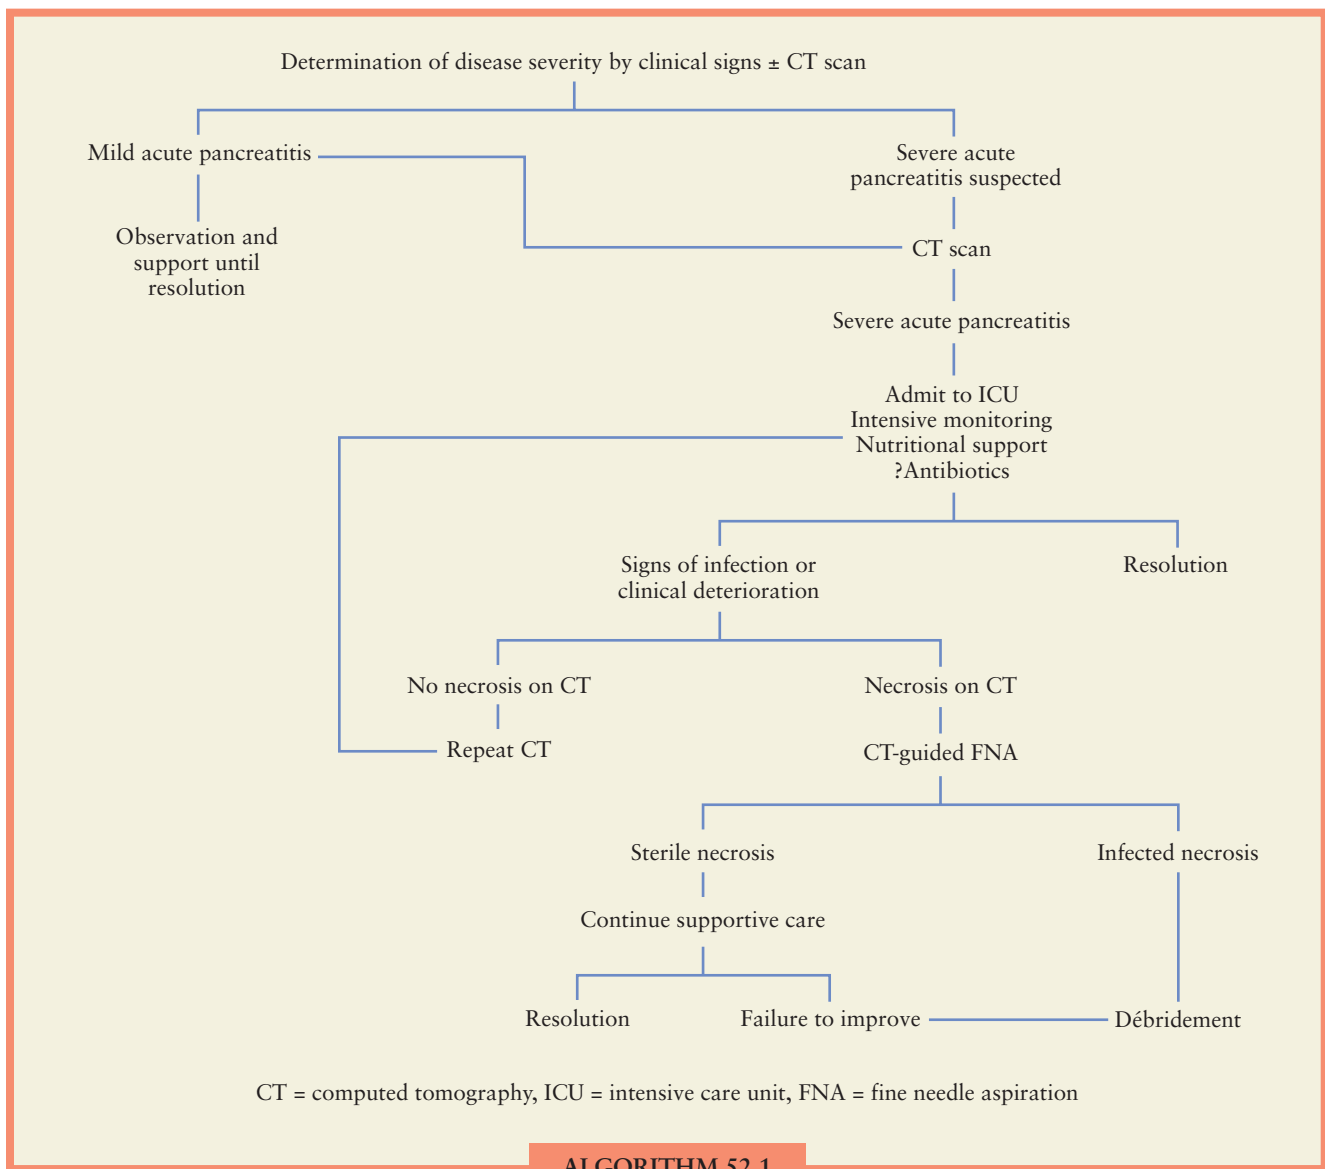

Initial clinical trials failed to demonstrate a benefit of prophylactic antibiotics; however, these studies were flawed by the inclusion of patients with mild disease who were at low risk for developing infected necrosis and the use of antibiotics with poor penetration into the pancreas. Trials were published in the 1990s showing a significant reduction in the incidence of pancreatic infection among patients receiving antibiotic prophylaxis, and based on this evidence, the use of antibiotic prophylaxis in patients documented to have necrotizing pancreatitis has become a widespread practice. Several recent trials that failed to show a benefit for prophylactic antibiotics have now been published.^{25,26} Similarly, recent meta-analyses of the available trials have failed to demonstrate a benefit for patients receiving prophylactic antibiotics.^{27,28} Disadvantages of using prophylactic antibiotics include the risks of fungal superinfection and the selection of resistant organisms. Another strategy for prophylaxis against infection in patients with acute pancreatitis has been the administration of probiotic bacteria to reduce the load of pathogenic bacteria in the bowel; however, prospective evaluation has yielded disappointing results.²⁹

An algorithm for the general management of acute pancreatitis and pancreatic necrosis is shown in Algorithm 52.1.

Pseudocysts. *Acute fluid collections* develop in up to 30% to 50% of patients with acute pancreatitis. As most resolve spontaneously, no specific treatment directed at acute fluid collections is necessary in the absence of evidence that the fluid is infected. However, in up to 10% of patients with acute pancreatitis, these fluid collections progress to develop a wall of fibrous granulation tissue, at which point they are classified as *pseudocysts*. The walls of pseudocysts generally require at least 4 weeks from the onset of pancreatitis to develop. Pseudocysts are distinguished from true cysts, which have epithelium-lined walls.

Most pseudocysts are asymptomatic; however, they can cause upper abdominal pain, gastric outlet obstruction, and obstructive jaundice. They also have the potential to rupture, to bleed, and to become infected.

Pseudocysts are usually diagnosed on ultrasonography or CT scanning (Fig. 52.5). It is important to distinguish pseudocysts from cystic neoplasms of the pancreas, as these lesions can be malignant or have malignant potential. These lesions are being

ALGORITHM 52.1

ALGORITHM 52.1. Algorithm for the management of acute pancreatitis.

FIGURE 52.5. Computed tomography scan of pancreatic pseudocyst.

diagnosed with increasing frequency due to the routine use of CT and MRI scans. Cystic neoplasms of the pancreas can usually be differentiated from pseudocysts by the lack of evidence for antecedent pancreatitis or pancreatic trauma, or by the appearance on imaging studies. Pseudocysts are typically round and unilocular and have a dense wall. Fine-needle aspiration, either by an image-guided percutaneous approach or an endoscopic ultrasound-guided approach, can be used in cases where it is difficult to differentiate between pseudocysts and cystic neoplasms. Most pseudocysts communicate with the pancreatic duct; hence, pseudocysts usually contain fluid with high amylase concentrations. In contrast, most neoplastic cysts do not communicate with the pancreatic duct and contain fluid with low amylase concentrations. These criteria, however, lack absolute predictive power.

The management of pseudocysts continues to evolve. In the past, surgical drainage of pseudocysts was recommended for all pseudocysts (even if asymptomatic) that persisted beyond a 6-week period of observation. This recommendation was based on a widely quoted report that suggested that pseudocysts that persist more than 6 weeks rarely resolve spontaneously and are associated with high complication rates.³⁰ However, more recent reports suggest that the natural history of asymptomatic pseudocysts follows a more benign course, with most pseudocysts less than 6 cm in diameter resolving spontaneously without complications.^{31,32}

Current well-accepted indications for intervention include the presence of symptoms attributable to the pseudocyst and growth during a period of observation. Whether large (>6 cm in diameter), asymptomatic pseudocysts that remain stable in size should undergo drainage is controversial.

10 There are multiple treatment options available for the treatment of pancreatic pseudocysts, including percutaneous aspiration, percutaneous drainage, and internal drainage (performed surgically or endoscopically). The optimal indications for these procedures are not fully determined, and the various procedures have not been compared in a controlled trial. Surgical drainage is the best validated procedure and is associated with high efficacy and a low recurrence rate. Percutaneous aspiration alone is associated with high recurrence rates. Patients with chronic pancreatitis or pancreatic ductal abnormalities, particularly a stricture or a discontinuity of the pancreatic duct in the setting of a communication between the pseudocyst and the pancreatic duct, have a high rate of failure with percutaneous drainage. Percutaneous drainage alone should be avoided in these circumstances.³³ Endoscopic cystgastrostomy

is an option for patients in whom the pseudocyst is intimately adherent to the posterior wall of the stomach; however, high rates of bleeding-related complications have been reported in some series. Avoidance of surgical drainage was achieved in just under half of patients through the use of endoscopic and percutaneous procedures in one series. Operations performed on patients who were initially treated nonoperatively were associated with a greater morbidity rate than cases in which surgery was the initial pseudocyst intervention.³⁴

The most commonly performed surgical procedures used to treat pseudocysts include cystgastrostomy, cystoduodenostomy, and Roux-en-Y cystjejunostomy. Cystgastrostomy or cystoduodenostomy applicable if a portion of the pseudocyst wall is adherent to the stomach or duodenum respectively allowing for the creation of anastomosis. Otherwise, the cyst wall can be anastomosed to a Roux limb of jejunum. These procedures, which can be performed as open or laparoscopic operations, should be delayed until pseudocyst wall maturation occurs. Mortality rates associated with surgical drainage procedures average less than 5%, with pseudocyst recurrence rates averaging 10%.

CHAPTER 53 ■ CHRONIC PANCREATITIS

NICHOLAS J. ZYROMSKI AND THOMAS J. HOWARD

KEY POINTS

- 1 Habitual alcohol use is responsible for 70% of chronic pancreatitis cases in the Western world; however, the precise pathophysiology of this disease is complex, incompletely understood, and almost certainly multifactorial.
- 2 Up to 90% of patients with chronic pancreatitis will experience pain at some point in their disease process. In contrast, 10% of patients will have painless pancreatitis.
- 3 Abdominal computed tomography is an excellent first test in the diagnosis of chronic pancreatitis; other diagnostic modalities include magnetic resonance imaging (MRI), endoscopic retrograde pancreatography (ERP), and endoscopic ultrasonography (EUS).
- 4 Medical treatment of chronic pancreatitis involves abstinence from ethanol and tobacco, as well as pancreatic enzyme replacement.
- 5 Surgical therapy may be required to treat mechanical complications of chronic pancreatitis such as biliary and duodenal stricture; however, the most common surgical indication is for treatment of pain.
- 6 Pancreatic anatomic changes in chronic pancreatitis are widely heterogeneous; selecting the proper operation for individual patients is crucial to obtain excellent outcomes.
- 7 Pancreas-directed operations may involve resection (pancreaticoduodenectomy, distal pancreatectomy, Beger operation), drainage (lateral pancreaticojejunostomy), or a combination of both resection and drainage (Frey operation).

Chronic pancreatitis (CP) has been defined by the Cambridge International Workshop on Pancreatitis as a “continuing inflammatory disease of the pancreas typically characterized by irreversible morphologic change and typically causing pain and/or permanent loss of function” [of the pancreas].¹ In 2010, the pathogenesis of CP is poorly understood, and no one ideal treatment currently exists. This vexing disease challenges clinicians and researchers alike; nevertheless, a significant number of patients afflicted with CP require medical attention. Surgical intervention targets the complications of CP; the heterogeneous nature of the disease mandates good clinical judgment to match the appropriate operation with the pathologic anatomy. In well-selected patients, the appropriate operation can provide durable relief of symptoms.

EPIDEMIOLOGY

The lack of a simple, consistent definition of CP hinders epidemiologic research. Estimates of CP incidence are widely variable—ranging from 1.6/100,000 new cases per year in Switzerland to as many as 14/100,000 new cases per year in the Cantabria region of Spain.^{2,3} In the United States, it has been estimated that the incidence and prevalence of CP are 4/100,000 and 13/100,000, respectively.⁴ With more widespread use of contemporary imag-

ing modalities and a better understanding of underlying genetic predisposition to CP, future estimates will likely reveal an increased incidence and prevalence of chronic pancreatitis.

ETIOLOGY AND PATHOGENESIS

- 1 The principal cause of CP in the Western world is habitual alcohol use (up to 70% of patients).⁴ Contemporary investigation supports the concept that the etiopathology of CP is complex and almost certainly multifactorial. Recognition of the fact that alcohol alone seldom causes CP and that only a small percentage (5%) of alcohol abusers will ever develop CP, in conjunction with the discovery of pancreatitis-associated gene mutations,⁵ led to the proposal of the TIGAR-O classification system (toxic/metabolic factors; idiopathic, genetic predispositions; autoimmune, recurrent, and severe acute pancreatitis; and obstructive pancreatitis). This system allows organization and assessment of individual interacting risk factors and provides a framework for instituting risk-reduction strategies and specific therapy. Individual components of the TIGAR-O system are shown in Table 53.1.

Over the past 50 years, several theories have been proposed to explain the development of CP. In 1946, Comfort et al.⁶ from the Mayo Clinic reported 29 patients with CP, concluding that

TABLE 53.1**CLASSIFICATION OF CHRONIC PANCREATITIS BY THE TIGAR-O SYSTEM**

T	<i>Toxic and metabolic factors</i> Alcohol—increasing incidence of CP with duration of alcohol use Tobacco—etiology unknown
I	<i>Idiopathic</i> Early onset—mean age 20; pain predominant; calcification rare Late onset—mean age 56; relatively painless; calcification, endocrine, and exocrine insufficiency present Minimal change—abdominal pain syndrome; minimal pancreatic changes on imaging studies Tropical pancreatitis—tropical calcific and fibrocalciculous pancreatic diabetes
G	<i>Genetic predispositions</i> PRSS1—cationic trypsinogen cannot be inactivated CFTR—cystic fibrosis transmembrane conductance regulator mutation; cannot hydrolyze mucus SPINK1—inactivates trypsin inhibitor
A	<i>Autoimmune</i> Lymphoplasmacytic sclerosing pancreatitis; increased IgG-4; increased association with other autoimmune diseases
R	<i>Recurrent and severe acute pancreatitis</i> Recurrent bouts of acute pancreatitis lead to chronic pancreatitis
O	<i>Obstructive</i> Stricture in main pancreatic duct leads to upstream (to the tail) ductal dilation, acinar atrophy, and chronic pancreatitis Caused by trauma, sphincter of Oddi dysfunction, pancreas divisum, sequelae of acute pancreatitis

Reproduced with permission from Etamad B, Whitcomb DC. Chronic pancreatitis: diagnosis, classification, and new genetic developments. *Gastroenterology* 2001;120(3):682–707.

the disease was caused by repeated bouts of acute pancreatitis. Nearly 20 years later, the consensus conference on CP in Marseille proposed that chronic pancreatic ductal obstruction (with proteinaceous and calcium plugs) was the underlying factor precipitating CP.⁷ More recently, a hypothesis was advanced suggesting that toxic metabolites in the form of free oxygen radicals lead to increased lipid peroxidation and oxidative stress.⁸ Clinical and basic investigations have supported this hypothesis. Nearly 50 years after the work of Comfort, their idea was revisited in the form of the necrosis-fibrosis hypothesis.⁹ This hypothesis suggests that repeated bouts of acute pancreatitis lead to focal areas of necrosis, which are eventually replaced by fibrotic tissue. The central role of pancreatic stellate cells has received significant attention in this regard.¹⁰

Significant insight into CP pathophysiology has been gained from seminal work defining hereditary pancreatitis. In 1996, Whitcomb et al.⁵ discovered a point mutation in the cationic trypsinogen gene (PRSS1). This mutation eliminates a fail-safe hydrolysis site in the trypsin molecule, subsequently rendering the molecule immune to inactivation by autolysis. Two other genetic mutations have subsequently been identified in patients with idiopathic CP. These genes encode the cystic fibrosis transmembrane conductance regulator (CFTR) and

the pancreatic secretory trypsin inhibitor (SPINK1).^{11–13} These discoveries provide insight into the molecular mechanisms of CP and advance diagnostic possibilities.

CLINICAL PRESENTATION

The clinical presentation of patients with CP involves pain, malabsorption (exocrine insufficiency), and diabetes mellitus (endocrine insufficiency). It is surprising that the interval between symptom onset and time of CP diagnosis ranges from 30 to 60 months.¹⁴ Several factors likely play a role in this delay in diagnosis, including (i) unreliability of alcoholic patients (the most common etiology of CP); (ii) nonspecificity of abdominal pain; (iii) difficulty in diagnosing idiopathic CP; and (iv) difficulty in diagnosing the small percentage (7%) of patients with painless CP. It is not unusual for morphologic changes of CP to exist for some time before symptoms occur.

2 The vast majority of patients with CP experience abdominal pain. Typical CP pain is described as located in the epigastrium and boring through the abdomen to the midback. In some cases, the pain is felt to wrap around the right or left flank in a bandlike nature. The pain may or may not be exacerbated by eating and is often worse at night.

More than 90% of acinar function must be lost before symptoms of malabsorption appear.¹⁵ Steatorrhea (fat malabsorption) usually precedes azotorrhea (protein malabsorption). Patients with steatorrhea complain of loose foul-smelling stools that appear greasy and float on the surface of the toilet bowl. Fat malabsorption may be accompanied by crampy abdominal pain and bloating. Weight loss and protein-calorie malnutrition commonly accompany malabsorption.

Most patients with CP will experience glucose intolerance at some point of their disease, and up to 60% will require insulin replacement. Endocrine insufficiency is due to a combination of decreased insulin production (as disease progresses and islet cell volume decreases) as well as a blunted insulin response. Diabetic ketoacidosis is rare; it seems that only a small amount of endogenous insulin/glucagon is necessary to prevent brittle diabetes.

DIAGNOSIS

The diagnosis of chronic pancreatitis is notoriously difficult in the early stages of the disease. The ideal gold standard for diagnosis of CP is histologic tissue analysis. Biopsy of the pancreas, however, is hazardous and not commonly available. Four principal modalities are currently used to image the pancreatic duct and pancreatic parenchyma: abdominal computed tomography (CT), magnetic resonance imaging (MRI), endoscopic retrograde pancreatography (ERP), and endoscopic ultrasound (EUS).

Radiologic Imaging

Identification of pancreatic calcification either on plain abdominal x-ray or on abdominal CT is pathognomonic for the disease; in this situation, the diagnosis of CP may be made with 90% confidence.⁴ Abdominal CT is the first noninvasive imaging test of choice in diagnosis and should be performed with a specific pancreas protocol—i.e., with water as gastrointestinal contrast and scanning both without intravenous contrast (to detect calcification) as well as with intravenous contrast in the arterial and portal venous phase. This test is widely available, easy to interpret, and allows visualization of the entire pancreas and surrounding structures (Fig. 53.1).

Recent advances in MRI technique, including the application of secretin-stimulated imaging, have led to increased utility of this noninvasive test, particularly at dedicated pancreatic centers. Like CT, MRI allows visualization of the entire pancreas and peripancreatic tissues in cross section. In addition,

FIGURE 53.1. Abdominal computed tomography scan without contrast in a patient with chronic pancreatitis demonstrating marked parenchymal calcification.

image reformatting allows performance of magnetic resonance cholangiopancreatography (MRCP), which offers a specific view of the pancreatic ductal system (Fig. 53.2). Magnetic resonance imaging is noninvasive and avoids the use of ionizing radiation. However, this test is simply diagnostic and does not afford the potential for intervention offered by endoscopic imaging tests.

Endoscopic Imaging

Historically, ERP has played an important role not only in diagnosis but also in treatment of patients with chronic pancreatitis. Changes in the pancreatic ducts observed on ERP include dilation and irregularity of side branches in early disease, with significant main duct changes (stricturing, irregularity, tortuosity, calcification, and cysts) occurring as CP progresses (Fig. 53.3). The small but significant potential for complications (bleeding, perforation, acute pancreatitis) accompanying ERP must be weighed against the potential benefits of diagnosis (in more difficult cases) and the ability to provide therapeutic intervention.

FIGURE 53.2. Magnetic resonance cholangiopancreatography (MRCP) in a patient with chronic pancreatitis and a narrow main pancreatic duct stricture downstream in the head. Note moderate biliary dilatation, marked main pancreatic duct dilatation, and dilation of side-branch pancreatic ducts in the uncinate process and tail of the gland.

FIGURE 53.3. Endoscopic retrograde pancreatogram (ERP) in the same patient presented in Figure 53.2. This patient was treated successfully by pancreatic duct stenting.

Tremendous recent advances in the technique and application of endoscopic ultrasound have led to its increased use for diagnosing CP. Sonographic features of CP include irregularity of the pancreatic duct, hyperechoic duct margins, and hyperechoic stranding in the pancreatic parenchyma (Fig. 53.4). Data are accumulating that attempt to correlate these changes with parenchymal histology.¹⁶ Advantages of EUS include its relative noninvasive nature, the ability to biopsy discrete lesions with great precision, and the ability to collect tissue (by fine-needle or core-needle biopsy) and pancreatic juice. The major disadvantage of EUS is the potential for significant intraobserver variability. Nevertheless, as further work to standardize definitions of sonographic CP evolves, it is likely that EUS will play an increasingly important role in the future.

Functional Tests

Pancreatic exocrine insufficiency invariably accompanies chronic pancreatitis; however, it is not necessarily diagnostic of CP. Tests of pancreatic exocrine function are mostly invasive

FIGURE 53.4. Endoscopic ultrasound image of a patient with chronic pancreatitis. Note hyperechoic pancreatic duct edges and large stone (stone) with posterior shadowing in the pancreatic head. Conf, confluence of superior mesenteric and splenic vein; PD, pancreatic duct; genu, genu of pancreatic duct.

TABLE 53.2**COMPLICATIONS OF CHRONIC PANCREATITIS**

Pain	90%
Pseudocyst	25%–30%
Biliary stricture	10%–15%
Mesenteric venous thrombosis	5%–10%
Duodenal stricture	4%–5%
Pseudoaneurysm	2%–3%
Pancreatic adenocarcinoma	2%–4% ^a
Extrapancreatic malignancy	10%–15%

^aRisk of pancreatic cancer is 2% after 10 years and 4% after 20 years with chronic pancreatitis; Lowenfels AB, Maisonneuve P, Cavallini G, et al. Pancreatitis and the risk of pancreatic cancer. International Pancreatitis Study Group. *N Engl J Med* 1993;328(20):1433–1437.

(i.e., collecting pancreatic juice by ERP before and after secretin stimulation), and are performed only at a few major pancreatic centers. In addition, results of these tests have been difficult to compare between centers. In general, pancreatic function tests have a limited role in diagnosing CP.

COMPLICATIONS

A wide variety of symptomatic and anatomic complications accompany the progression of CP. Of these complications, pain, pseudocyst, and biliary stricture are the most common (Table 53.2).

Pain

More than 90% of patients with CP have symptoms of abdominal pain at some point during the course of their disease. The mechanisms responsible for CP pain are incompletely understood but likely involve multiple factors including acute and chronic inflammation of pancreatic nerves as well as increased pancreatic ductal and interstitial pressure.¹⁷

Exocrine/Endocrine Insufficiency

Virtually all patients with CP demonstrate impaired exocrine function. This exocrine insufficiency is generally mild in the early course of the disease process. Patients with moderate to severe exocrine insufficiency should be treated by pancreatic enzyme replacement. Glucose intolerance appears later in the course of the disease (usually after 8–10 years). Patients with CP should undergo regular screening for endocrine insufficiency.

Pseudocyst

The true incidence of pseudocyst complicating CP is difficult to accurately identify, but likely ranges from 25% to 30%.^{18,19} Pseudocysts by definition arise after disruption of main or side-branch ducts and may be solitary or multiple. Treatment of pseudocysts is informed by defining the underlying pancreatic ductal anatomy. It is worth mention that the classic teaching that all pseudocysts greater than 5 to 6 mm in size should be treated is no longer accepted by most pancreatic surgeons. Currently, indications for treating pseudocysts are related strictly to symptoms.²⁰

Pseudoaneurysm

Pseudoaneurysms of the visceral arterial tree are generally seen in patients with concomitant pseudocysts. Interventional radiologic treatment (i.e., transarterial coiling) is successful in arresting hemorrhage in almost 100% of cases.

Biliary Stricture

Chronic inflammation and scarring in the pancreatic head leads to stricture of the intrapancreatic bile duct in up to 50% of patients. Many of these strictures are mild (in fact, clinical jaundice is generally preceded by asymptomatic elevation of alkaline phosphatase); however, between 10% and 15% of patients with CP will develop symptomatic jaundice requiring treatment.

Duodenal Obstruction

Pancreatic head inflammatory changes and/or compression by pseudocysts lead to duodenal obstruction in 4% to 5% of patients with CP.

Mesenteric Venous Thrombosis

The true incidence of splenic vein thrombosis in the setting of CP is unknown but may occur in as many as 5% to 10% of patients. Splenic vein thrombosis leads to left-sided (sinistral) portal hypertension, and clinically significant upper gastrointestinal hemorrhage from gastric varices may ensue. Most contemporary pancreatic surgeons reserve treatment of splenic vein thrombosis (i.e., splenectomy) for patients who have suffered a significant bleeding episode; prophylactic splenectomy has fallen out of favor.²¹ Similarly, it is difficult to estimate the incidence of superior mesenteric vein and extrahepatic portal vein thrombosis in CP. Collateral venous formation (cavernous transformation) in this setting significantly complicates operations targeting the pancreatic head.

Cancer

The specter of pancreatic cancer looms large in all patients with CP. Lowenfels et al.²² showed the incidence of pancreatic cancer to be 1.8% after 10 years with CP and 4% after 20 years. Chronic inflammatory changes and fibrosis of the pancreatic parenchyma make the diagnosis of pancreatic cancer quite difficult in the setting of CP. It is notable that CP patients have a significantly elevated risk of developing extrapancreatic malignancy (10%–15%), primarily in the upper and lower airway and gastrointestinal tract.

THERAPY

Pain is the main symptom in CP, and although concomitant treatment of the physiologic derangements that occur in these patients such as diabetes mellitus (endocrine insufficiency) and steatorrhea (exocrine insufficiency) are important factors in improving an individual's overall quality of life, pain control remains the central focus for most patients. Due to the poorly understood nature of pain in patients with chronic pancreatitis and the lack of high-quality controlled clinical trials in treatment, no established standards of care exist. To fill this void, the American Gastroenterological Association developed an algorithm for treatment guidelines progressing from less-invasive to more-invasive therapies.²³ The first step in management of patients with CP should be targeted at lifestyle

changes, specifically the avoidance of alcohol and tobacco. Total abstinence of alcohol can result in pain relief in up to 50% of patients, albeit mainly those with mild to moderate disease.²⁴ Miyake et al.²⁵ demonstrated pain relief in 60% of those patients who discontinued or reduced alcohol intake, whereas in the group of patients who continued drinking, spontaneous pain relief was only 26%. Similarly, cigarette smoking is associated with a higher risk of developing chronic pancreatitis and increases the likelihood of developing pancreatic calcifications, a structural change that may influence the yearly number of painful relapses.^{26,27} Tobacco cessation in patients with established chronic pancreatitis reduces the risk of developing pancreatic calcifications.²⁸

- 5 Treating patients with supplemental pancreatic enzymes has been hypothesized to work by stimulating receptors in the proximal small intestine to trigger a negative-feedback loop that suppresses baseline pancreatic enzyme secretion, decreasing ductal pressures and thereby decreasing pain. Several studies have been published with widely varying enzyme preparations, dosages, and outcome measurements. To date, the exact efficacy of this frequently used treatment modality remains unclear.^{29,30}

If lifestyle modifications and medical treatment including pancreatic enzyme supplementation and the judicious use of narcotic and nonnarcotic analgesics fail to control symptoms, more invasive endoscopic and percutaneous techniques should be considered. The role of endoscopic therapy for pain in patients with CP involves sphincterotomy, lithotripsy, and pancreatic duct stenting.³¹ While some of these interventions have shown significant promise, these results are largely confined to small cohorts of patients in specialized centers and have focused specifically on short-term outcome measurements. Celiac plexus blockade with a steroid (triamcinolone) plus an anesthetic agent (bupivacaine) or complete neurolysis (absolute alcohol) has been used both percutaneously and via endoscopic ultrasound (EUS) as a method of blocking the transmission of pain impulses from the celiac plexus to the central nervous system in patients with pancreatic cancer and CP.³² While it appears that EUS is more efficacious than percutaneous methods due presumably to better visualization of the celiac plexus leading to a more targeted injection of neurolytic agent, these techniques require further evaluation in well-designed clinical trials.³³

SURGERY FOR COMPLICATIONS OF CP

Biliary Obstruction

This local complication of CP results from either fibrotic stricturing of the distal common bile duct as it traverses the head of the pancreas or through compression of the intrapancreatic biliary segment by the inflammatory enlargement and microcystic disease in the pancreatic head. It is reported to occur in approximately 6% (3%–32%) of hospitalized patients with CP and is found in 35% (15%–60%) of patients undergoing surgical intervention for CP.³⁴ Significant biliary obstruction is commonly defined as an elevated alkaline phosphatase greater than two times the upper limit of normal values in the laboratory used associated with radiographic evidence of biliary dilatation. Although it is tempting to manage these fibrotic biliary strictures initially with endoscopic therapy, the long-term success rates with this modality are disappointing.³⁵ Self-expanding metal stents have been used in a highly selected population of 13 patients unable to undergo operative bypass, with good results reported after a mean of 50 months.³⁶ Choledochoduodenostomy or hepaticojejunostomy Roux-en-Y are the operations of choice to simply relieve the biliary tract obstruction,³⁴ although most surgeons would employ a pancreatic head resection as described below to treat both the inflammatory pancreatic head mass as well as the concomitant biliary tract obstruction.

Duodenal Obstruction

Obstruction of the duodenum due to CP is either acute or chronic. Acute obstruction is usually transient and related to the severe inflammatory process occurring in the pancreas and retroperitoneum during an acute attack and as such, has the potential to resolve once the pancreatic inflammation subsides. Chronic duodenal obstruction occurs from repeated inflammatory insults resulting in cicatricial stenosis and fibrosis of the duodenum. These structural alterations will not resolve when the pancreatic inflammation subsides. Although chronic duodenal obstruction is a rare complication, occurring in 1.2% (0.5%–13%) of hospitalized patients with CP, it can be found in up to 13% (2%–36%) of patients requiring surgical intervention.³⁴ Similar to biliary obstruction, its specific treatment is a gastrojejunostomy, although most surgeons would relieve this obstruction using a pancreatic head resection.

Pancreatic Pseudocysts/Pseudoaneurysms

Complicated pseudocysts that frequently occur in patients with CP are commonly associated with an underlying pancreatic duct abnormality, and their surgical treatment should take these facts into account.¹⁸ Patients with pseudocysts and CP should not be treated by cyst drainage solely, as is often the case in patients with a pseudocyst following a bout of acute pancreatitis, because the underlying anatomic and morphologic abnormalities are left untreated, leading to a high incidence of recurrence.¹⁹ Patients with CP frequently require some form of pancreatic duct drainage, and at times, a parenchymal resection to treat the underlying anatomic abnormality that contributed to the formation of the pancreatic pseudocyst.

Less common complications occur as a consequence of fibrotic stricturing of adjacent organs including the biliary tract (elevated alkaline phosphatase, transaminases, and a dilated common bile duct) or duodenum (early satiety, weight loss, inability to eat); most of these complications can be addressed by the judicious application of one of the aforementioned operative procedures.

Pseudoaneurysms that occur as a consequence of severe inflammation and in patients with chronic pancreatitis are commonly related to a pseudocyst. Their presentation is that of bleeding, either into an established pseudocyst causing an increase in abdominal pain, or rarely through the ampulla of Vater (hemosuccus pancreaticus) or freely into the abdominal cavity (hemoperitoneum). Mesenteric angiography can detect the source of bleeding from the splenic, gastroduodenal, superior and inferior pancreaticoduodenal arteries in 94% of cases.³⁷ Angiographic embolization for control is generally the treatment of choice. Following control of hemorrhage and stabilization of the patient's clinical course, formal pancreatic resection of the involved pancreas may be carried out.

Incapacitating Abdominal Pain

Failure of both medical management and minimally invasive measures of pain control require careful counseling with the patient regarding the options for continued management. Some evidence exists that spontaneous pain relief occurs during the clinical course of the disease with progressive glandular destruction resulting in endocrine and exocrine insufficiency, although this may take up to 15 years from diagnosis.³⁸ The duration of pain, however, remains woefully unpredictable, limiting the enthusiasm for “watchful waiting.”³⁹ Recently, two randomized controlled trials (RCT) in patients with chronic pancreatitis were published, which demonstrated a relative equivalence between surgical and endoscopic therapy in short-term pain relief, with surgery having a significant advantage in durability of pain reduction.^{40,41} Given these findings, perhaps surgical therapy should not be viewed as the last resort in patients with painful chronic pancreatitis.

FIGURE 53.5. Surgical treatment options in patients with chronic pancreatitis based on pancreatic ductal morphology.

6 Operations for patients with chronic pancreatitis can be divided into four basic types: resection, drainage, combined resection and drainage, and denervation. Due to the morphologic heterogeneity of the disease in different patients, choosing the correct operation for any individual patients with chronic pancreatitis comes from interpreting the results of published clinical experience when applied to different anatomic and morphologic subsets. Dominant anatomic abnormalities found in patients with chronic pancreatitis can be broken down into three groups, either large duct, small duct, or minimal change variants based on the anatomic configuration of their main pancreatic duct (Fig. 53.5). Large duct variants have a cross-sectional diameter of their main pancreatic duct of 7 mm whereas small duct variants have a main pancreatic duct diameter of less than this.⁴² Minimal change pancreatitis describes a group of patients who have symptoms of the disease but few or no anatomic changes in

their gland or duct to confirm this.⁴³ In the small duct variant of chronic pancreatitis, there are three specific subgroups: large pancreatic head, small pancreatic head, and obstructive pancreatitis. The precise measurements of a large, hypertrophic pancreatic head have not been specifically defined, but enlargement is generally considered to be greater than 3 cm when measured in AP diameter on cross-sectional imaging.⁴⁴ Obstructive pancreatitis occurs in the setting of a physiologically significant stricture of the main pancreatic duct with upstream (toward the spleen) changes of pancreatic duct dilatation, blunted side branches, and parenchymal inflammation.⁴⁵

For some anatomic subsets, several different operations may be successfully applied. An example is in patients with small duct, enlarged head chronic pancreatitis where either pancreaticoduodenectomy or the Beger or Frey-type duodenal preserving pancreatic head resection can be successfully used depending on the specific patient characteristics and surgeon preferences. The following paragraphs provide a brief description of the operations currently available to treat patients with chronic pancreatitis.

FIGURE 53.6. Gastrointestinal reconstruction after pylorus-preserving pancreaticoduodenectomy.

FIGURE 53.7. Operative photograph demonstrating the "cored-out" pancreatic head and uncinate process in a patient undergoing the Beger operation. The patient's head is to the right, the asterisk is at the junction of the second and third portion of the duodenum; the line parallels the superior mesenteric vein/portal vein path.

FIGURE 53.8. Drawing illustrating longitudinal pancreaticojejunostomy.

Resection Operations. Pancreaticoduodenectomy (PD), either the classic or pylorus-preserving variant, is the traditional resection operation used in patients with chronic pancreatitis.⁴⁶ It removes the head of the pancreas, duodenum, and distal common bile duct, a region of the pancreas that has been regarded as the “pacemaker” of the disease (Fig. 53.6). This operation is generally applied to small duct variants and has the flexibility to be used in both large and small head subtypes.

The Beger operation, termed one of the duodenal-preserving pancreatic head resection (DPPHR) procedures, involves transecting the pancreatic neck followed by a subtotal resection of the pancreatic head, removing diseased

tissue in the head and uncinate process (Fig. 53.7) while preserving the normal relationship and function of the duodenum and distal common bile duct.⁴⁷ This operation is applied to patients with small duct chronic pancreatitis and a large, hypertrophic pancreatic head. It has also been selectively used with good overall results in patients with small duct chronic pancreatitis and normal pancreatic heads (pancreas divisum).⁴⁸

Distal pancreatectomy removes pancreatic parenchyma to the left of the confluence of the splenic vein with the portal vein (body and tail of the pancreas). This operation is used very selectively in patients with obstructive chronic pancreatitis.^{45,49}

FIGURE 53.9. Operative photograph of the Frey operation: longitudinal pancreaticojejunostomy with “coring-out” of the pancreatic head. The patient’s head is at the 12 o’clock position; the *asterisk* is on the junction of the second and third portion of the duodenum.

A high-grade pancreatic duct stricture in the body or tail of the pancreas with upstream (toward the spleen) side-branch changes and evidence of pancreatic inflammation is the key to diagnosis. Care should be taken to evaluate these strictures for the possibility of pancreatic cancer.

Extended distal pancreatectomy (95% pancreatectomy) was advanced in the 1970s and 1980s as a better option for patients with CP.⁵⁰ Careful follow-up of these patients showed poor long-term outcomes, particularly with regard to brittle diabetes, and this operation has been abandoned.⁵¹ It is worthwhile to note that experience gained performing 95% pancreatectomy led to the development of the Frey duodenal preserving pancreatic head resection described later.

Total pancreatectomy with or without islet cell transplantation removes the entire pancreas and is currently limited in its applicability to patients with chronic pancreatitis outside of clinical trials using salvage procedures for the pancreatic islets with isolation and reinfusion as an islet cell transplant, or for patients with no other therapeutic options.⁵² It is used optimally in patients with small duct or minimal change chronic pancreatitis who have not undergone prior resection or drainage procedures.

Drainage Operation. The Partington-Rochelle modification of the Puestow procedure, a longitudinal pancreaticojejunostomy is the classic operation used to treat patients with large duct pancreatitis by decompressing the entire length of the pancreatic duct (head to tail) into a defunctionalized (Roux-en-Y) limb of jejunum (Fig. 53.8).⁵³

Combined Resection and Drainage. The Frey operation is the other procedure termed as a duodenal-preserving pancreatic head resection (DPPHR), but in contrast to the Beger operation, the pancreatic neck is not transected. The surgeon identifies the pancreatic duct in the neck of the pancreas and then opens the duct longitudinally by following it down into the pancreatic head and out to the tail. In the pancreatic head, the surgeon then cores out pancreatic tissue from the pancreatic duct outward until just a thin rim of tissue remains around the head of the pancreas contiguous with the duodenum. A defunctionalized limb of jejunum (Roux-en-Y) is then anastomosed side to side to the pancreatic duct in the body and tail and to the remaining rim of pancreatic tissue in the head to effect complete drainage of the entire gland (Fig. 53.9). This operation is perhaps the most versatile as it can be applied to patients with either small or large duct chronic pancreatitis as well as patients with either large or normal pancreatic head size.⁵⁴

Denervation Operations. Bilateral thoroscopic splanchnicectomy is a minimally invasive approach to splanchnic denervation used to treat pain in patients with chronic pancreati-

tis.⁵⁵ Candidates are generally patients with no other surgical targets (i.e., minimal change pancreatitis) who have been shown to have a splanchnic mediated pain pathway based on their response to a differential epidural anesthetic.

Clinical Results following Operation in Patients with CP

In measuring the results of surgery in patients with chronic pancreatitis, long-term success is typically defined by a thorough clinical follow-up of at least 5 years' duration.⁵⁶ When restricting data to long-term outcome measures, the results for pancreatic head resections (DPPHR and PD) are as shown in Table 53.3. In a recent meta-analysis, DPPHRs have been shown to be equivalent in outcome to pancreaticoduodenectomy (PD) in the measured variables of pain relief, overall morbidity, and incidence of postoperative endocrine insufficiency.⁵⁷ In this same analysis, DPPHRs were judged to be superior to PD in terms of operative time, postoperative hospital stay, and overall quality of life measures.

In a comparison of the two most common DPPHRs, the Beger operation and the Frey operation, no significant differences were found in a controlled randomized clinical trial when patients were followed for more than 8 years (Table 53.4).⁵⁸

Outcomes of patients with chronic pancreatitis treated by longitudinal/lateral pancreaticojejunostomy (drainage operation) are shown in Table 53.5. After a mean follow-up of 79 months, 72% of patients experienced either complete or partial pain relief following operation with a mean perioperative mortality rate in this group of patients of only 1%.

A surgical denervation procedure as exemplified by bilateral thoroscopic splanchnicectomy is a minimally invasive treatment of chronic pancreatitis with low perioperative morbidity and mortality rates. Based on currently available data, complete or partial pain relief is achieved in only 50% of patients during long-term clinical follow-up (Table 53.6).

CONCLUSION

Various operations are available to treat the heterogeneous complications of chronic pancreatitis. Surgeons who accept care of these challenging patients must be well versed in several therapeutic strategies, and committed to following these patients closely for the long term to ensure optimal clinical outcomes. Future advances in the therapy of chronic pancreatitis will be predicated on obtaining a better understanding of the underlying pathophysiology.

CHAPTER 54 ■ NEOPLASMS OF THE EXOCRINE PANCREAS

ATTILA NAKEEB AND KEITH D. LILLEMOR

KEY POINTS

- 1 There is increasing evidence that ductal pancreatic cancer arises from precursor lesions referred to as pancreatic intraepithelial neoplasia (PanIN) with progression from proliferative lesions without nuclear abnormality to carcinoma in situ, known as PanIN-3.
- 2 Intraductal papillary mucinous neoplasms (IPMNs) are intraductal mucin-producing tumors that range from benign adenomas to invasive carcinoma and should be considered for resection.
- 3 Spiral computed tomography scan is the preferred noninvasive imaging test for the diagnosis and staging of pancreatic cancer demonstrating the primary lesion and its relationship to adjacent visceral vessels as well as metastatic disease to the liver and peritoneum.
- 4 Perioperative mortality rates following pancreaticoduodenectomy have fallen to the range of 2% to 5%, although perioperative complications occur in approximately 40% of patients.
- 5 The survival rate after pancreaticoduodenectomy for pancreatic cancer is approximately 20%, with factors influencing survival including tumor size, margin status, and node status.
- 6 Although some controversy exists, most data support the role for adjuvant therapy, either chemotherapy or chemoradiation, for patients following resection of pancreatic cancer.
- 7 Surgical palliation of patients with pancreatic cancer located in the head found to be unresectable at laparotomy includes biliary bypass, gastrojejunostomy, and chemical splanchnicectomy to palliate the symptoms of jaundice, duodenal obstruction, and pain, respectively.

In the United States, it is estimated that nearly 42,470 new cases of pancreas cancer will be diagnosed, with almost 35,240 people dying of the disease in 2009. Pancreatic cancer is the fourth leading cause of cancer death in this country.¹ Currently, only 15% to 20% of patients diagnosed with pancreatic adenocarcinoma are candidates for pancreatic resection. Five-year survival averages 15% to 20% for patients with resected disease and only 3% for all stages combined.² The nonspecific symptoms associated with early pancreatic cancer, the inaccessibility of the pancreas to examination, the aggressiveness of the tumors, and the technical difficulties associated with pancreatic surgery make pancreatic cancer one of the most challenging diseases treated by general surgeons. In recent years, significant advances have been made in our understanding of the pathogenesis and clinical management of pancreatic cancer. This chapter will review the epidemiology and risk factors associated with pancreatic cancer, discuss recent developments in the field of molecular genetics, and provide an update on the current clinical management of pancreatic cancer.

EPIDEMIOLOGY AND RISK FACTORS

In the United States, approximately 11 new cases of pancreatic cancer are diagnosed per 100,000 population annually.¹ Although the incidence rate of pancreatic cancer has been relatively stable during the last two decades, it has increased nearly threefold since the beginning of the last century (Fig. 54.1). It has been argued that the apparent increase in the incidence of pancreatic cancer may represent a misclassification of pancreatic cancer as other types of upper gastrointestinal cancer, particularly gastric cancer, in the past. However, several analyses indicate that a portion of the threefold increase in the

incidence of pancreatic cancer has been real. The risk for the development of pancreatic cancer is related to age, race, sex, tobacco use, diet, and specific genetic syndromes (Table 54.1). The incidence increases with advancing age. More than 80% of cases occur in persons between the ages of 60 and 80 years, and pancreatic cancer is rare in people younger than 40 years. The incidence and mortality rates for pancreatic cancer in African Americans of both sexes are higher than those in whites. The gender differences in pancreatic cancer have been equalizing during recent years. Pancreatic cancer is still more common in men than in women, but the incidence and mortality rates have increased in women, while they have stabilized or slightly decreased in men.¹

Environmental and dietary factors have also been implicated as risk factors for the development of pancreatic cancer. The most consistently observed environmental risk for the development of pancreatic cancer is cigarette smoking. It has been estimated that cigarette smoking can increase the risk for pancreatic cancer between one and a half and five times. The mechanism is unknown, but carcinogens in cigarette smoke have been shown to produce pancreatic cancers in laboratory animals. In addition, autopsy studies have documented hyperplastic changes in pancreatic ductal cells with atypical nuclear patterns in smokers. Alcohol consumption does not seem to be a risk factor for pancreatic cancer despite conflicting past reports. Recent studies suggest that past studies linking pancreatic cancer to alcohol use may have been confounded by tobacco use. Similarly, coffee consumption and exposure to ionizing radiation have been shown not to be associated with an increased pancreatic cancer risk.

Several epidemiologic investigations have suggested that diet may play an important role in the development of pancreatic cancer. An apparent association has been noted between pancreatic cancer and an increased consumption of total calories, carbohydrate, cholesterol, meat, salt, dehydrated food,

FIGURE 54.1. U. S. age-adjusted death rates for pancreatic carcinoma.

fried food, refined sugar, soy beans, and nitrosamines. The risks are unproven for the ingestion of fat, β -carotene, and coffee. A protective effect has been reported for dietary fiber, vitamin C, fruits, and vegetables.³

In addition to well-defined genetic syndromes, a number of common conditions have been thought to be etiologic factors in the development of pancreatic cancer. An apparent association between diabetes and pancreatic cancer has been suggested. Approximately 80% of patients diagnosed with pancreatic cancer have impaired glucose metabolism, impaired glucose tolerance, or diabetes mellitus. It is unclear if alterations in glucose tolerance/metabolism are a causative factor for pancreatic cancer or represent reaction to an enlarging malignancy in the pancreas. Among patients with newly diagnosed diabetes, 0.85% went on to be diagnosed with pancreatic cancer within 3 years.⁴

Type 2 diabetes of at least 5 years' duration has been shown to increase the risk of pancreas cancer twofold.

The risk of pancreatic cancer has been shown to increase as body mass index increases. Examination of data from the Nurses' Health Study and the Health Professionals' follow-up study show a 1.72 relative risk (95% confidence interval [CI], 1.19–2.48) of pancreatic cancer in patients with a body mass index (BMI) greater than 30 kg/m² as compared to individuals with a BMI less than 23 kg/m².⁵

Chronic pancreatitis of any cause has been associated with a 25-year cumulative risk for the development of pancreatic cancer of approximately 4%. Other conditions for which a possible association with pancreatic cancer has been demonstrated include thyroid and other benign endocrine tumors, cystic fibrosis, and pernicious anemia.

TABLE 54.1

RISK FACTORS FOR PANCREATIC CANCER

	■ INCREASED RISK	■ POSSIBLE RISK	■ UNPROVED RISK
Demographic factors	Advancing age Male sex Black race	Geography	Socioeconomic status Migrant status
Host factors	Hereditary nonpolyposis colorectal cancer Familial breast cancer Peutz-Jeghers syndrome Ataxia-telangiectasia Familial atypical multiple mole melanoma Hereditary pancreatitis		Peptic ulcer surgery
Environmental factors	Tobacco	Diet Occupation	Alcohol Coffee Radiation

AD, autosomal dominant; FAMMM, familial atypical multiple mole melanoma; HNPCC, hereditary nonpolyposis colorectal cancer.

Most cases of pancreatic cancer have no obvious predisposing factors. However, it is believed that between 5% and 10% of pancreatic cancers arise because of a familial predisposition. Six genetic syndromes have been associated with an increased risk for the development of pancreatic cancer (Table 54.2). These include hereditary nonpolyposis colon cancer, familial breast cancer associated with the *BRCA2* mutation, Peutz-Jeghers syndrome, ataxia-telangiectasia syndrome, familial atypical multiple mole melanoma syndrome, and hereditary pancreatitis.

MOLECULAR GENETICS

Tremendous advances have been made in understanding the molecular genetics of pancreatic cancer in recent years. In general, the genes involved in the pathogenesis of pancreatic cancer can be divided into three categories: tumor-suppressor genes, oncogenes, and DNA mismatch-repair genes (Table 54.3).

Tumor-suppressor genes normally function to control cellular proliferation. When these genes are inactivated by genetic events such as mutation, deletion, chromosome rearrangements, or mitotic recombination, their function as growth suppressors can be lost, and abnormal growth regulation is the result. The tumor-suppressor genes *p53*, *p16*, *DPC4*, and *BRCA2* are frequently inactivated in sporadic adenocarcinoma of the pancreas. The function of *p53* appears to be inactivated in up to 75% of all pancreatic cancers. The *p53* gene product is a DNA-binding protein that acts as both a cell cycle checkpoint and an inducer of apoptosis. Inactivation of the *p53* gene in pancreatic cancer leads to the loss of two important controls of cell growth: regulation of cellular proliferation and induction of cell death. The *p16* gene encodes a protein that binds cyclin to cyclin D–Cdk4 complexes. When the *p16* gene product binds to these complexes, it inhibits the phosphorylation of a number of growth and regulatory proteins. Inactivation of *p16* leads to the loss of an important cell cycle checkpoint and therefore relatively unchecked proliferation. *DPC4* is a tumor-suppressor gene that has been identified on chromosome 18q. This chromosome has been shown to be missing in nearly 90% of pancreatic cancers. The *DPC4* gene is inactive in almost 50% of pancreatic carcinomas. The mutation appears to be a homozygous deletion in 30% of pancre-

atic cancers and a point mutation in another 20% of tumors. *DPC4* mutations are more specific than *p53* or *p16* mutations for pancreatic cancer. The function of *BRCA2* has not been established, but the gene product appears to be a tumor suppressor participating in DNA damage repair. Mutations in *BRCA2* have been linked to hereditary breast and ovarian cancers. Recent studies also suggest a significantly increased risk of pancreatic cancer development in patients with germline *BRCA2* mutations.

Oncogenes are derived from normal cellular genes called *proto-oncogenes*. When overexpressed or activated by mutation, oncogenes encode proteins with transforming properties. Activating point mutations in the *K-ras* oncogene is the most common genetic alteration in pancreatic cancer. Point mutations in

codons 12, 13, or 61 of the *K-ras* oncogene impair the intrinsic guanosine triphosphatase activity of its gene product; the result is a protein that is constitutively active in signal transduction. Mutations of *K-ras* have been found in 80% to 100% of pancreatic cancers and therefore may prove useful in the development of a molecular screening test for pancreatic cancer.

Mismatch-repair genes function to ensure the accuracy of DNA replication, and when these genes are mutated, errors in DNA replication are not repaired. The human mismatch-repair genes are *hMSH2*, *hMLH1*, *hPMS1*, *hPMS2*, *hMSH6/GTBP*, and *hMSH3*. The enzymes encoded by these genes repair single base-pair changes and small insertions and deletions that occur during DNA replication. Approximately 4% of pancreatic cancers can be characterized by disorders of DNA mismatch-repair genes.⁶

PATHOLOGY

Tumors of the exocrine pancreas can be classified based on their cell of origin (Table 54.4). The most common neoplasms of the exocrine pancreas are ductal adenocarcinomas. Approximately 65% of pancreatic ductal cancers arise in the head, neck, or uncinate process of the pancreas; 15% originate in the body or the tail of the gland; and 20% diffusely involve the whole gland.

Solid Epithelial Tumors

Ductal Adenocarcinomas. Ductal adenocarcinomas account for more than 75% of all nonendocrine pancreatic cancers. Grossly, they are white–yellow, poorly defined, hard masses that often obstruct the distal common bile duct or main pancreatic

FIGURE 54.2. Microscopic appearance of ductal adenocarcinoma of the head of the pancreas demonstrating glands from an adenocarcinoma embedded in a fibrous matrix.

duct. They are often associated with a desmoplastic reaction that causes fibrosis and chronic pancreatitis. Microscopically, they contain infiltrating glands of varying size and shape surrounded by dense, reactive fibrous tissue (Fig. 54.2). The epithelial cells sometimes form papillae and cribriform structures, and they frequently contain mucin. The nuclei of the cells can show marked pleomorphism, hyperchromasia, loss of polarity, and prominent nucleoli.

Ductal adenocarcinomas tend to infiltrate into vascular, lymphatic, and perineural spaces. At the time of resection, most ductal carcinomas have already metastasized to regional lymph nodes. In addition to the lymph nodes, pancreatic ductal adenocarcinomas frequently metastasize to the liver (80%), peritoneum (60%), lungs and pleurae (50% to 70%), and adrenal glands (25%). They also can directly invade the duodenum, stomach, transverse mesocolon, colon, spleen, and adrenal glands.

The histologic examination of a pancreas resected for cancer frequently reveals the presence of precursor lesions in the pancreatic ducts and ductules adjacent to the cancers.⁷ This suggests that much like colon cancer, which arises from benign adenomas, pancreatic cancer may also demonstrate progression to malignant from benign precursor lesions. These precursor lesions are referred to as pancreatic intraepithelial neoplasia (PanIN). Briefly, PanIN-1A and PanIN-1B are proliferative lesions without remarkable nuclear abnormality that have a flat and papillary architecture, respectively. PanIN-3 is associated with severe architectural and cytonuclear abnormalities, but invasion through the basement membrane is absent. The older term for PanIN-3 includes carcinoma in situ (CIS). PanIN-2 is an intermediate category between PanIN-1 and PanIN-3 and is associated with a moderate degree of architectural and cytonuclear abnormality.⁸ Several lines of evidence suggest that PanINs are precursors of infiltrating pancreatic cancer: PanINs are often found in association with ductal adenocarcinomas, three-dimensional mapping techniques have demonstrated a stepwise transformation from mild dysplasia to severe dysplasia in pancreatic duct lesions, and PanINs demonstrate some of the same genetic changes seen in infiltrating adenocarcinomas, most notably activating point mutations in codon 12 of *K-ras* and mutations in the *p16* and *p53* tumor-suppressor genes.

Adenosquamous Carcinomas. Adenosquamous carcinoma is a rare variant of ductal adenocarcinoma that shows both glandular and squamous differentiation. This variant appears to be more common in patients who have undergone

previous chemoradiation therapy. The biologic behavior of adenosquamous carcinoma appears to be similar to that of ductal adenocarcinoma, with similar rates of perineural invasion, lymph node metastases, and dissemination.

Acinar Cell Carcinomas. Acinar cell carcinomas account for only 1% of pancreatic exocrine tumors. Acinar tumors are typically smooth, fleshy, lobulated, hemorrhagic, or necrotic. Histologically, they form acini, and the cells display an eosinophilic, granular cytoplasm. Immunohistochemical staining demonstrates expression of trypsin, lipase, chymotrypsin, or amylase. These tumors are more common in males, with a male-to-female predominance of approximately 3:1. The age of diagnosis is usually in the fifth to seventh decades. These tumors tend to be larger than ductal adenocarcinomas, often being larger than 10 cm. Although data are limited, it appears that patients with acinar cell carcinoma have a slightly better prognosis than patients with ductal carcinoma.⁹ Therefore, surgical resection is the treatment of choice.

Giant Cell Carcinomas. Giant cell carcinomas account for fewer than 1% of nonendocrine pancreatic cancers. They tend to be large, with average diameters greater than 15 cm. Microscopically, they contain large, uninucleated or multinucleated tumor cells, many of which are pleomorphic. The nuclei contain prominent nucleoli and numerous mitotic figures. Giant cell carcinomas are associated with a poorer prognosis than ductal adenocarcinomas. There is a variant of giant cell carcinoma termed *giant cell carcinoma with osteoclastlike giant cells*. These lesions tend to be well circumscribed with nonpleomorphic giant cells and are less aggressive than standard giant cell carcinomas.

Pancreatoblastoma. Pancreatoblastomas occur primarily in children ages 1 to 15 years. Pancreatoblastomas contain both epithelial and mesenchymal elements. The epithelial component appears to arise from acinar cells. The tumors are typically larger than 10 cm and often contain areas of degeneration and hemorrhage. The prognosis appears to be more favorable than that for typical ductal adenocarcinoma if the tumor can be resected.

Cystic Epithelial Tumors

Cystic neoplasms also arise from the exocrine pancreas. Cystic neoplasms are less common than ductal adenocarcinomas, tend to occur in women, and are evenly distributed throughout the gland. Many pancreatic and peripancreatic cysts are actually benign inflammatory pseudocysts. It is important to identify cystic neoplasms because their management is very different from that of nonneoplastic cysts. With advancements in imaging technology, cystic lesions of the pancreas are being detected with increased frequency. As many as 1% of individuals undergoing cross-sectional abdominal imaging are found to have pancreatic cysts. Although many of these lesions are small and asymptomatic, they can have malignant potential. Therefore, the management of these patients is complex, and knowledge of pancreatic cyst natural history and predictors of neoplasia are important.

Serous Cystic Neoplasms. Serous cysts are epithelial neoplasms composed of uniform cuboidal glycogen-rich cells that usually form numerous small cysts containing serous fluid. Serous cystadenomas or microcystic adenomas are more common in women than in men (2:1 preponderance). These tumors can vary from a few centimeters to more than 10 cm in size. Twenty-five percent to 30% of patients are asymptomatic; however, most patients present with symptoms such as abdominal or epigastric pain, dyspepsia, nausea, or vomiting. Serous cystadenomas can be located any-

where in the pancreas—head, body, or tail—and usually do not communicate with the pancreatic ducts. Plain computed tomography (CT) shows a honeycomb pattern of microlacunae, with thin septa separating different segments. Serous cystic neoplasms can have a sunburst pattern of central calcification, which is seen in 10% to 30% of cases. Grossly, they appear as spongy, well-circumscribed, multiloculated cysts. Microscopically, they consist of a layer of simple cuboidal cells separated by dense fibrous bands. Most serous cystic neoplasms are benign, although malignant behavior has been reported rarely (i.e., metastases to the liver or peripancreatic lymph nodes). Symptomatic cysts or cysts that cannot be differentiated from other potentially malignant cysts should undergo surgical excision. Recently, it has been suggested that cysts greater than 4 cm in size should also be resected since they demonstrate a significant increased growth rate compared to smaller cysts.¹⁰

Mucinous Cystic Neoplasms. Mucinous cystic neoplasms (MCNs) are neoplasms composed of mucin-producing epithelial cells associated with an ovarian type of stroma. These cysts usually do not communicate with the larger pancreatic ducts. MCNs are relatively uncommon but account for almost 30% of all cystic neoplasms. The mean age at diagnosis is between 40 and 50 years. MCNs are more common in women, with a female-to-male ratio of 9:1. Most patients with MCNs present with vague abdominal symptoms that include epigastric pain or a sense of abdominal fullness. The majority (70% to 90%) of MCNs arise in the body or tail of the pancreas, and only a minority (10% to 30%) involve the head of the gland. Microscopically, the cysts are lined by tall, columnar, mucin-producing epithelium. These columnar cells have basal nuclei and abundant intracytoplasmic apical mucin and can form flat sheets or papillae. The walls of the cysts contain a very distinctive “ovarian-type” stroma. This stroma is composed of densely packed spindle cells with sparse cytoplasm and uniform elongated nuclei. All MCNs are considered to be premalignant lesions and should be completely resected to prevent progression to malignancy.

Invasive mucinous cystadenocarcinomas are MCNs associated with an invasive carcinoma, whereas noninvasive mucinous neoplasms can be categorized into mucinous cystic neoplasms with low-grade dysplasia (adenoma), mucinous cystic neoplasms with moderate dysplasia (borderline), and mucinous cystic neoplasms with high-grade dysplasia (carcinoma in situ) based on the degree of architectural and cytologic atypia of the epithelial cells. Approximately one third of all MCNs are associated with invasive carcinoma. Patients with mucinous cystadenocarcinomas tend to be 5 to 10 years older than patients with benign MCNs. The extent of invasive and in situ carcinomas in MCNs can be very focal. Therefore, a benign diagnosis cannot be established on biopsy alone and the lesions should be completely resected. The prognosis for patients with resected benign or borderline tumors is excellent. Patients with mucinous cystadenocarcinoma tend to do better than patients with ductal adenocarcinoma, with a 5-year survival of approximately 50%.

2 Intraductal Papillary-Mucinous Neoplasms. Intraductal papillary-mucinous neoplasms (IPMNs) are intraductal mucin-producing neoplasms with tall, columnar, mucin-containing epithelium with or without papillary projections. These neoplasms extensively involve the main pancreatic ducts and/or major side branches. In addition, IPMNs lack the ovarian stroma characteristic of MCNs. Similar to the well-defined adenoma–carcinoma sequence in pancreatic ductal adenocarcinoma (PanIN to invasive ductal carcinoma), IPMNs seem to follow a similar pattern progressing from IPMN adenoma, to borderline IPMN with dysplasia, to IPMN with CIS, and eventually to invasive carcinoma. Microscopically, they consist of papillary projections lined by columnar

TABLE 54.5

DIAGNOSIS

COMPARISON BETWEEN MUCINOUS CYSTIC NEOPLASM (MCN) AND INTRADUCTAL PAPILLARY MUCINOUS NEOPLASM (IPMN)

	■ MCN	■ IPMN

mucin-secreting cells. They show varying degrees of cellular atypia. The mean age of patients with invasive carcinoma is approximately 5 years older than patients with noninvasive IPMNs, suggesting an approximate 5-year lag period for progression to malignancy.

IPMNs are subclassified as main- and branch-duct types and as a mixed type that contains elements of both. Main-duct IPMN is characterized by involvement of the duct of Wirsung, which is dilated to more than 1 cm in diameter. Branch-duct IPMN originates in the side branches of the pancreatic ductal system and appears as a multilobular cystic lesion communicating with a nondilated main pancreatic duct. Typically, branch-duct IPMN occurs in the uncinate process or head of the gland, but it can also be seen in the neck and distal pancreas. If the main duct is dilated with synchronous involvement of the branch ducts, it is described as a mixed IPMN.

IPMNs are usually found in individuals in their 60s to 80s. Some patients may experience symptoms that include abdominal pain, steatorrhea, weight loss, jaundice, diabetes, and chronic pancreatitis. A substantial number of these lesions are also detected as incidental findings on cross-sectional imaging studies performed for other indications. IPMNs appear to be more common in the head, neck, and uncinate process of the pancreas but can be found diffusely throughout the whole gland. CT scans will typically reveal a cystic mass in the head of the pancreas that appears to communicate with the pancreatic ductal system. On endoscopy, mucin can be seen oozing from the ampulla of Vater. Endoscopic retrograde cholangiopancreatography (ERCP) can be used to confirm that the cysts communicate with the pancreatic ducts.

MCNs are the main entity to consider in the differential diagnosis of IPMNs (Table 54.5). Two morphologic features distinguish IPMNs from MCNs: IPMNs communicate with ducts, while mucinous cysts do not; IPMNs also lack an ovarian stroma that is present in mucinous cysts. In addition, mucinous cysts are usually seen in the tail of the pancreas and occur in middle-aged women, whereas IPMNs are found in the head of the pancreas and occur in older individuals of either sex.

As noted, IPMNs represent a continuum of disease from benign to malignant. In a large series of resected IPMNs from the Johns Hopkins Hospital,¹¹ the prognosis for the benign forms of the disease appears to be significantly better than for invasive IPMNs with 1-, 2-, and 5-year actuarial survivals of 97%, 94%, and 77%, respectively. Although invasive IPMNs are associated with disease progression and death, the prognosis remains markedly better than for invasive ductal carcinoma of the pancreas with survivals of 72%, 58%, and 43% at 1, 2, and 5 years, respectively. It is unclear whether this fact is due to earlier presentation or differences in tumor biology.

International consensus guidelines for the management of IPMNs have been developed.¹² The guidelines suggest that patients with a main-duct component to their IPMN (i.e., main and mixed types) should be optimally managed with surgical resection since at least 60% of these lesions have evidence of malignancy (either carcinoma in situ or invasive cancer) in the resected specimen. The management of branch-type IPMNs, however, remains controversial. The guidelines suggest that branch-type IPMNs less than 3 cm can be safely observed if they are asymptomatic and have no concerning radiographic or cytopathologic evidence of malignancy (mural nodules or abnormal cytology of cyst fluid). The guidelines further suggest a management strategy for branch-type IPMNs based on size. For lesions less than 1 cm in size, management entails serial cross-sectional imaging. For lesions 1 to 3 cm, management entails cross-sectional imaging, endoscopic ultrasound, and cytology. In patients with lesions 1 to 3 cm in size, surgical management is considered for symptoms or concerning radiographic (e.g., mural nodules, main-duct dilation) or cytopathologic evidence of malignancy. For lesions greater than 3 cm, surgical management is recommended even in the absence of other concerning features of malignancy. Again, the decision to resect must be individualized based on a variety of considerations. These include patient age, patient compliance for a surveillance program, and the quality of a surveillance program, which can vary according to available resources.

The goal of surgical therapy for IPMNs should be a complete surgical resection yielding negative margins for all invasive and noninvasive disease. Unlike those patients with completely resected noninvasive MCNs (who are routinely cured), patients with completely resected noninvasive IPMNs should undergo careful follow-up and surveillance for the development of recurrent disease. Furthermore, patients with resected invasive IPMNs should also undergo careful follow-up and surveillance as they, too, remain at risk for the development of recurrent disease.

Solid Pseudopapillary Tumor. Solid pseudopapillary tumors (SPTs), also termed solid and cystic tumors, papillary cystic tumors, *Hamoudi tumors*, and *Frantz tumor*, occur primarily in women in their third to fourth decade of life. Grossly, the masses range from 5 to 15 cm in diameter. The tumors show solid, cystic, and papillary components. Although most patients are cured after resection, metastases have been reported in a small number of cases.

CLINICOPATHOLOGIC STAGING

Accurate pathologic staging of pancreatic cancer is important for providing prognostic information to patients and for

TABLE 54.6**STAGING****AMERICAN JOINT COMMITTEE ON CANCER STAGING OF PANCREATIC CANCER**

■ STAGE	■ T	■ N	■ M	■ 5-Y SURVIVAL (%)

comparing the results of various therapeutic trials. The American Joint Committee on Cancer (AJCC) staging for pancreatic cancer is shown in Table 54.6. This system, based on the TNM classification, takes into account the extent of the primary tumor (T), the presence or absence of regional lymph node involvement (N), and the presence or absence of distant metastatic disease (M).

DIAGNOSIS

Clinical Presentation

Many of the difficulties associated with the management of pancreatic cancer result from our inability to make the diagnosis at an early stage. The early symptoms of pancreatic cancer include anorexia, weight loss, abdominal discomfort, and nausea. Unfortunately, the nonspecific nature of these symptoms often leads to a delay in the diagnosis. Specific symptoms usually develop only after invasion or obstruction of nearby structures has occurred. Most pancreatic cancers arise in the head of the pancreas, and obstruction of the intrapancreatic portion of the common bile duct leads to progressive jaundice, acholic stools, darkening of the urine, and pruritus. Pain is a common symptom of pancreatic cancer. The pain usually starts as vague upper abdominal or back pain that is often ignored by the patient or attributed to some other cause. It is usually worse in the supine position and is often relieved by

leaning forward. Pain may be caused by invasion of the tumor into the splanchnic plexus and retroperitoneum and by obstruction of the pancreatic duct. Other digestive symptoms are also common in pancreatic cancer (Table 54.7).

Occasionally, pancreatic cancer may be discovered in an unusual manner. The onset of diabetes may be the first clinical feature in 10% to 15% of patients. An episode of acute pancreatitis may also be the initial presentation of pancreatic cancer if the tumor partially obstructs the pancreatic duct. It is important to consider a pancreatic cancer in patients presenting with acute pancreatitis, especially those without an obvious cause for their pancreatitis (alcohol or gallstones).

The most common physical finding at the initial presentation is jaundice (Table 54.8). Hepatomegaly and a palpable gallbladder may be present in some patients. In cases of advanced disease, cachexia, muscle wasting, or a nodular liver, consistent with metastatic disease, may be evident. Other physical findings in patients with disseminated cancer include left supraclavicular adenopathy (Virchow node), periumbilical adenopathy (Sister Mary Joseph node), and pelvic drop metastases (Blumer shelf). Ascites can be present in 15% of patients.

Laboratory Studies

In patients with cancer of the head of the pancreas, laboratory studies usually reveal a significant increase in serum total bilirubin, alkaline phosphatase, and γ -glutamyl transferase,

indicating bile duct obstruction. The transaminases can also be elevated but usually not to the same extent as the alkaline phosphatase. In patients with localized cancer of the body and tail of the pancreas, laboratory values are frequently normal early in the course. Patients with pancreatic cancer may also demonstrate a normochromic anemia and hypoalbuminemia secondary to the nutritional consequences of the disease. In patients with jaundice, the prothrombin time can be abnormally prolonged. This usually is an indication of biliary obstruction, which prevents bile from entering the gastrointestinal tract and leads to malabsorption of fat-soluble vitamins and decreased hepatic production of vitamin K-dependent clotting factors. The prothrombin time can usually be normalized by the administration of parenteral vitamin K. Serum amylase and lipase levels are usually normal in patients with pancreatic cancer.

A wide variety of serum tumor markers have been proposed for use in the diagnosis and follow-up of patients with pancreatic cancer. The most extensively studied of these is CA 19-9, a Lewis blood group-related mucin glycoprotein. Approximately 5% of the population lacks the Lewis gene and therefore cannot produce CA 19-9. When a normal upper limit of 37 U/mL is used, the accuracy of the CA 19-9 level in identifying patients with pancreatic adenocarcinoma is only about 80%. When a higher cutoff value of more than 90 U/mL is used, the accuracy improves to 85%, and increasing the cutoff value to 200 U/mL increases the accuracy to 95%.¹³ The combined use of CA 19-9 and ultrasonography, CT, or ERCP can improve the accuracy of the individual tests, so that the combined accuracy approaches 100% for the diagnosis of pancreatic cancer. Levels of CA 19-9 have also been correlated with prognosis and tumor recurrence. In general, higher CA 19-9 values before surgery indicate an increased size of the primary tumor and increased rate of unresectability. In addition, the CA 19-9 level has been used to monitor the results of neoadjuvant and adjuvant chemoradiation therapy in patients. Increasing CA 19-9 levels usually indicate recurrence or progression of disease, whereas stable or declining levels indicate a stable tumor burden, absence of recurrence on imaging studies, and an improved prognosis.

Radiologic Investigations

Radiologic imaging plays a crucial role in the diagnosis, staging, and follow-up of patients with pancreatic cancer. In addition to identifying the primary tumor, the goals of imaging include the assessment of local and regional invasion, evaluation of lymph nodes and vascular structures, identification of distant metastatic disease, and determination of tumor resectability. Ultrasonography, CT, and magnetic resonance imaging (MRI) are all useful noninvasive tests in the patient suspected of having a pancreatic cancer.

Transabdominal ultrasonography is operator dependent but can demonstrate dilated intrahepatic and extrahepatic bile ducts, liver metastases, pancreatic masses, ascites, and enlarged peripancreatic lymph nodes. Pancreatic cancer typically appears as a hypoechoic mass on ultrasonography. Ultrasonography will reveal a pancreatic mass in 60% to 70% of patients with cancer. Because helical CT is just as sensitive as ultrasonography and provides more complete information about surrounding structures and the local and distant extent of the disease, transabdominal ultrasonography has been largely replaced by CT.

3 Helical or spiral CT is currently the preferred noninvasive imaging test for the diagnosis of pancreatic cancer. Pancreatic cancer usually appears as an area of pancreatic enlargement with a localized hypodense lesion (Fig. 54.3). For pancreatic lesions, a dual-phase intravenous contrast study is ideal. Thin cuts are obtained through the pancreas and liver during both an arterial phase and portal venous phase after the administration

FIGURE 54.3. Computed tomogram of the abdomen of a patient with adenocarcinoma of the pancreas. **A:** The obstructed and dilated common bile duct (*light arrow*) and pancreatic duct (*dark arrow*) can be seen. In the adjacent cross section (**B**), a large mass is present in the head of the pancreas (*arrow*).

of intravenous contrast. In addition to determining the primary tumor size, CT is used to evaluate invasion into local structures or metastatic disease.

In general, MRI offers no significant advantages over CT because of a low signal-to-noise ratio, motion artifacts, lack of bowel opacification, and low spatial resolution. MRI can be considered an alternative preoperative staging exam in patients with allergies to iodinated contrast agents and in patients with renal insufficiency. On MRI, a typical pancreatic adenocarcinoma appears hypointense on T1-weighted, unenhanced images, and has a variable appearance on T2-weighted sequences. The T2 signal of the tumor is often dependent on the amount of desmoplastic response associated

with the tumor. On dynamic imaging following a gadolinium contrast injection, an adenocarcinoma enhances relatively less than the background pancreatic parenchyma in the early phase and then reveals progressive enhancement in the subsequent phases. Magnetic resonance imaging with magnetic resonance cholangiopancreatography (MRCP) is currently indicated for noninvasive diagnostic imaging to evaluate the biliary and pancreatic ducts and may be the optimal method to survey patients with IPMN and the pancreatic remnant after surgery.

Traditionally, the next step in the evaluation of the jaundiced patient has been cholangiography, either by the endoscopic or by the percutaneous route. If the endoscopic approach is used, the duodenum and ampulla can be visualized and biopsy specimens obtained if necessary. In addition, ERCP allows for direct imaging of the pancreatic duct. The sensitivity of ERCP for the diagnosis of pancreatic cancer approaches 90%. The finding of a long, irregular stricture in an otherwise normal pancreatic duct is highly suggestive of a pancreatic cancer (Fig. 54.4). Often, the pancreatic duct will be obstructed with no distal filling. Although ERCP is reliable in confirming the presence of a clinically suspected pancreatic cancer, it should not be used routinely. Diagnostic ERCP should be reserved for patients with presumed pancreatic cancer and obstructive jaundice in whom no mass is demonstrated on CT, symptomatic but nonjaundiced patients without an obvious pancreatic mass, and patients with chronic pancreatitis who develop jaundice.

FIGURE 54.4. Endoscopic retrograde cholangiopancreatography in a patient with adenocarcinoma of the pancreas demonstrates a stricture of both the distal common bile duct and the pancreatic duct (*arrow*).

PREOPERATIVE STAGING

The goal of preoperative staging of pancreatic cancer is to determine the feasibility of surgery and the optimal treatment for each individual patient. In many cases, dynamic CT with oral and intravenous contrast may provide all the information necessary. With objective, specific anatomy-based CT criteria, patients with pancreatic cancer can be stratified into three distinct groups: (a) metastatic, defined by CT evidence of distant metastatic spread to the liver, peritoneum, or lung; (b) locally advanced, which is defined by CT evidence of arterial encroachment of the celiac axis or superior mesenteric artery or venous involvement or occlusion of the superior mesenteric or portal veins; and (c) potentially resectable, which is defined

FIGURE 54.5. Endoscopic ultrasonogram of a 2.2-cm mass in the head of the pancreas. The transducer tip is located in the duodenum. The dilated common bile duct and gallbladder (GB) can be seen at the top of the image. The pancreatic duct (PD) is also dilated. The mass involves the portal vein (PV).

as no CT evidence of extrapancreatic disease, a patent superior mesenteric vein (SMV)–portal vein confluence, and no evidence of direct tumor extension to the celiac axis or superior mesenteric artery. Up to 85% of potentially resectable patients can be resected, whereas only 20% of patients with locally advanced pancreatic cancer can be successfully resected.¹⁴ For tumors of the head, neck, or uncinate process of the pancreas, occlusion of the SMV or portal vein along with the presence of periportal collateral vessels is a sign of unresectability and typically precludes resection for cure. In contrast, for tumors of the body and tail of the pancreas, occlusion of the splenic vein with perigastric collaterals does not always preclude resection and should not be considered a sign of unresectability.

Endoscopic ultrasonography (EUS) is a minimally invasive technique in which a high-frequency ultrasonographic probe is placed into the stomach and duodenum endoscopically and the pancreas is imaged. Tumors appear as hypoechoic areas in the pancreatic substance (Fig. 54.5). The strengths of EUS techniques for pancreatic cancer are the clarification of small lesions (<2 cm) when CT findings are questionable or negative, detection of malignant lymphadenopathy, detection of vascular involvement, and the ability to perform EUS-guided fine-needle aspiration (FNA) for definitive diagnosis and staging. EUS is not effective in assessing metastatic disease to the liver. In patients for whom a tissue diagnosis is required (poor operative candidates or undergoing neoadjuvant therapy), EUS-guided FNA has been used to acquire tissue samples for cytologic analysis. This approach may avoid the risks of tumor seeding from percutaneous biopsy. The accuracy of EUS without FNA averages 85% for determining T-stage and 70% for determining N-stage disease. The combination of EUS and FNA has a sensitivity of 93% and a specificity of 100% for T-stage and an accuracy of 88% for N-stage disease.¹⁵ At the time of diagnosis, only 10% of patients have tumors confined to the pancreas, 40% have locally advanced disease, and more than 50% have distant spread.

Percutaneous FNA of pancreatic masses is helpful in selected patients. The technique is safe and generally reliable but is of limited use in patients in whom surgical exploration for attempted resection or palliation is planned. The reasons

for not using FNA or percutaneous biopsy in potentially resectable lesions are twofold. First, even after repeated sampling, a negative result does not exclude malignancy; in fact, it is the smaller and likely more curable tumors that are likely to be missed by the needle. The second concern is the potential for seeding of the tumor, either along the needle tract or with intraperitoneal spread. Percutaneous biopsy is primarily indicated in patients with unresectable cancers based on preoperative staging to direct palliative chemoradiation therapy or in patients with cancer in the head of the pancreas for whom neoadjuvant protocols are being considered. Currently, however, EUS is the preferred technique when possible in either situation.

STAGING LAPAROSCOPY

The use of diagnostic laparoscopy in pancreatic cancer remains controversial. Proponents believe that laparoscopy can identify a substantial number of unresectable patients with advanced disease and, therefore, should be uniformly applied to all patients with potentially resectable tumors.¹⁶ On the other hand, opponents believe that the inherent cost of such a practice far outweighs the benefit to the small number of patients in whom diagnostic laparoscopy is useful. The liver and peritoneum are the most common sites of distant spread of pancreatic carcinoma. Once distant metastases have developed, survival is so limited that a conservative approach is usually indicated. Liver metastases larger than 1 cm in diameter can usually be detected by CT, but approximately 30% of these metastases are smaller and therefore may not be routinely detected. Moreover, peritoneal and omental metastases are usually only 1 to 2 mm in size and frequently can be detected only by direct visualization. With the recent improvements in CT imaging, the rate of unsuspected positive peritoneal findings approaches 10% to 15% for all patients. The percentage, however, varies with tumor location. Patients presenting with obstructive jaundice secondary to tumors in the head of the pancreas typically have only a 15% to 20% incidence of unexpected intraperitoneal metastasis after routine staging studies. In contrast, unexpected peritoneal metastasis is found in up to 50% of patients with cancer of the body and tail of the pancreas.¹⁷

Selective use of staging laparoscopy should be considered for patients at high risk of occult metastatic disease (Table 54.9). The information gained from preoperative staging provides the basis for planning therapy for each individual patient. If

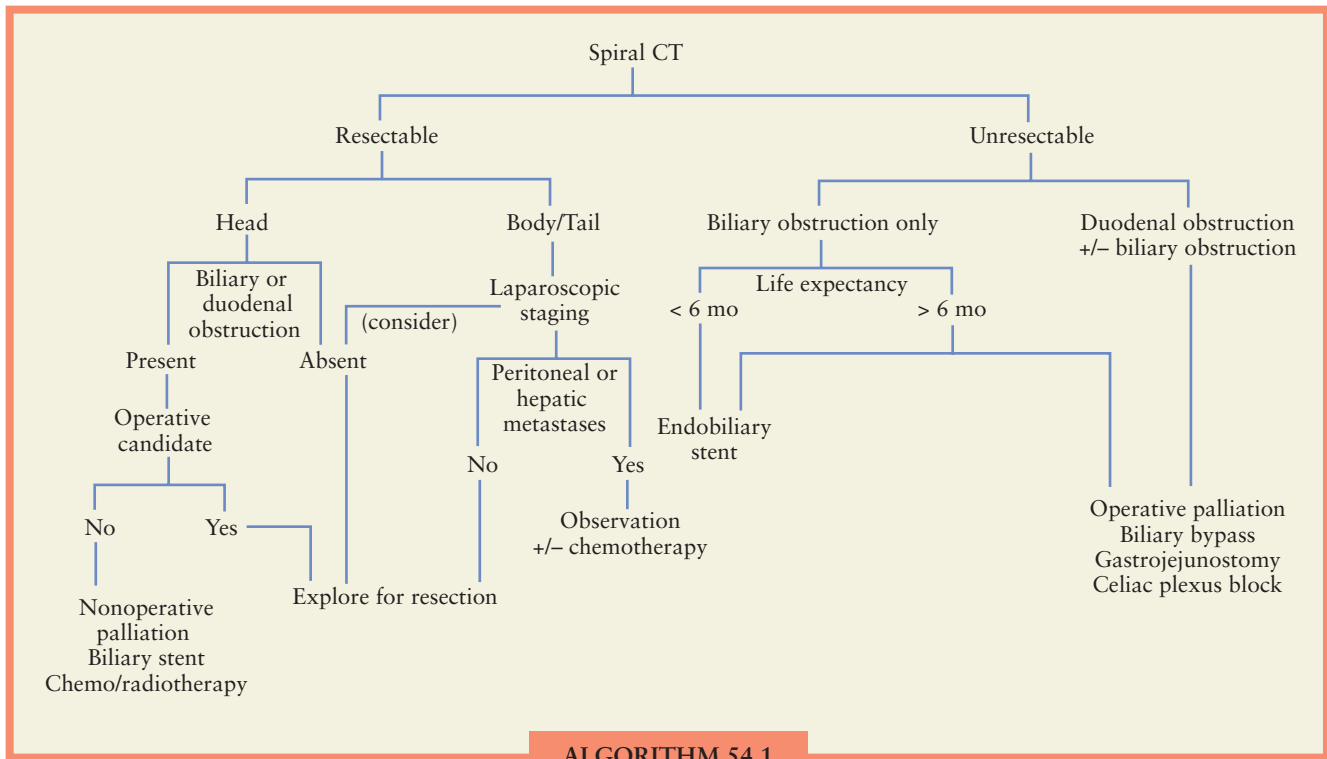

TABLE 54.9

DIAGNOSIS

SIGNS OF HIGH RISK OF OCCULT METASTATIC DISEASE

Large primary tumors
Lesions in the neck, body, or tail of the pancreas
Equivocal radiographic findings suggestive of occult distant metastatic disease
Low-volume ascites
CT findings indicating possible carcinomatosis
Small hypodense regions in the hepatic parenchyma that suggest hepatic metastases that are not amenable to percutaneous biopsy
Subtle clinical and laboratory findings suggesting more advanced disease (e.g., marked hypoalbuminemia and/or weight loss, significant increases in CA19–9 level, and relatively severe pain requiring narcotic analgesia)

CT, computed tomography.

ALGORITHM 54.1. Diagnosis and management of pancreatic cancer. (After Tsiotis GG, Sarr MG. Diagnosis and clinical staging of pancreatic cancer. In: Howard JM, Idezuki Y, Ihse I, et al., eds. *Surgical Disease of the Pancreas*, 3rd ed. Baltimore: Williams & Wilkins; 1998:510.)

the results of preoperative staging with CT/MRI and laparoscopy show localized disease, resectability rates may approach 90% for tumors in the head of the pancreas. A decision tree for the clinical staging of suspected pancreatic cancer is shown in Algorithm 54.1.

RESECTION OF PANCREATIC CARCINOMA

Carcinoma of the Head, Neck, or Uncinate Process

In 1912, Kaush¹⁸ reported the first successful resection of the duodenum and a portion of the pancreas for an ampullary cancer. In 1935, Whipple et al.¹⁹ described a technique for radical excision of a periampullary carcinoma. The operation was originally performed in two stages. A cholecystogastrostomy to decompress the obstructed biliary tree and a gastrojejunostomy to relieve gastric outlet obstruction comprised the first stage. The second stage was performed several weeks later when the jaundice had resolved and the nutritional status had improved. During the second stage, an en bloc resection of the second portion of the duodenum and head of the pancreas was performed without reestablishing pancreatic–enteric continuity. Although earlier contributions had been made, the report by Whipple et al. began the modern-day approach to the treatment of pancreatic carcinoma.

Since Whipple's original description, pancreaticoduodenal resection has undergone numerous modifications and technical refinements. Unfortunately, during most of the first 50 years when the procedure was performed, the reported morbidity and mortality rates were unacceptably high, and long-term survival rates were disappointing. During the late 1960s and 1970s, the high operative morbidity and mortality and poor

long-term survival rates led some surgeons to suggest that the Whipple procedure be abandoned. However, during the last two decades, a number of reports have documented improved operative results and long-term survival rates for patients with periampullary tumors following the Whipple procedure, so that a resurgence in its popularity has occurred.

The operative management of pancreatic cancer consists of two phases: first, assessing tumor resectability and then, if the tumor is resectable, completing a pancreaticoduodenectomy and restoring gastrointestinal continuity. After the abdomen has been opened through an upper midline or bilateral subcostal incision, a careful search for tumor outside the limits of a pancreaticoduodenal resection should be carried out. The liver, omentum, and peritoneal surfaces are inspected and palpated, and suspect lesions are sampled and specimens submitted for frozen section analysis. Next, regional lymph nodes are evaluated for tumor involvement. The presence of tumor in the periaortic lymph nodes of the celiac axis indicates that the tumor is beyond the limits of normal resection. However, the presence of tumor-bearing lymph nodes that normally would be incorporated within the resection specimen do not constitute a contraindication to resection.

Once distant metastases have been excluded, the primary tumor is assessed in regard to resectability. Local factors that preclude pancreaticoduodenal resection include retroperitoneal extension of the tumor to involve the inferior vena cava or aorta or direct involvement or encasement of the superior mesenteric artery, hepatic artery, and celiac axis. Involvement of the SMV or portal vein can be managed with venous resection and reconstruction in select cases. The technical aspects of determining local resectability begin with a Kocher maneuver and mobilization of the duodenum and head of the pancreas from the underlying inferior vena cava and aorta. Once the duodenum and head of the pancreas are mobilized sufficiently, the surgeon's hand can be placed under the duodenum and head of the pancreas to palpate the relationship of the tumor

mass to the superior mesenteric artery. Inability of the surgeon to identify a plane of normal tissue between the mass and the arterial pulsation indicates direct tumor involvement of the superior mesenteric artery, and the possibility of complete tumor resection is eliminated.

The final step to determine resectability involves dissection of the superior mesenteric and portal veins to rule out tumor invasion. Identification of the portal vein can be simplified greatly if the common hepatic duct is divided and reflected early in the dissection. Once the hepatic duct has been divided, the posteriorly located portal vein can be identified easily. After the anterior surface of the portal vein is dissected posterior to the neck of the pancreas, the next step is to identify the SMV and dissect its anterior surface. This is done most easily by extending the Kocher maneuver past the second portion of the duodenum to include the third and fourth portions of the duodenum. During this extensive Kocherization, the first structure that one encounters anterior to the third portion of the duodenum is the SMV. The anterior surface of the vein then can be cleaned rapidly and dissected under direct vision by retracting the neck of the pancreas anteriorly. The dissection is continued until it connects to the portal vein dissection from above.

Most experienced pancreatic surgeons, at this point, proceed with a pancreaticoduodenectomy without obtaining a tissue diagnosis. The clinical presentation, results of preoperative CT and cholangiography, and operative findings of a palpable mass in the head of the pancreas surpass the ability of an intraoperative biopsy to define the diagnosis of malignancy.

Having excluded regional and distant metastases and demonstrated no tumor involvement in major vascular structures, the surgeon can proceed with pancreaticoduodenectomy with a high degree of certainty that the tumor is resectable. In the pylorus-preserving modification of pancreaticoduodenectomy, the duodenum is first mobilized and divided approximately 2 cm distal to the pylorus. If a classic Whipple procedure is to be performed, the stomach is divided to include approximately 40% to 50% of the stomach with the resected specimen. The gastroduodenal artery is exposed, ligated, and divided near its origin at the common hepatic artery. It is always important to confirm, before ligation, that the structure to be ligated is indeed the gastroduodenal artery and not a replaced right hepatic artery. Next, the neck of the pancreas is divided, with care taken to avoid injury to the underlying superior mesenteric and portal veins. The portal and superior mesenteric veins are then dissected from the uncinate process and head of the pancreas. At this point, the fourth portion of the duodenum and the proximal jejunum are mobilized, with the proximal jejunum divided approximately 10 cm distal to the ligament of Treitz. The proximal jejunum and fourth portion of the duodenum are passed under the superior mesenteric vessels to the right, and the uncinate process is dissected from the superior mesenteric artery. The course of the superior mesenteric artery should be clearly identified to avoid injury to this structure. At this point, the specimen consisting of the gallbladder and common bile duct; the head, neck, and uncinate process of the pancreas; the entire duodenum; and the proximal jejunum (and the distal stomach for a traditional Whipple procedure) is freed completely and removed from the operative field (Fig. 54.6).

There are a number of techniques for restoring gastrointestinal continuity after a pancreaticoduodenal resection. Our preferred technique is to bring the end of the divided jejunum through the transverse mesocolon in a retrocolic fashion and perform an end-to-side pancreaticojejunostomy. The anastomosis is begun by placing a series of interrupted 3-0 silk sutures between the side of the jejunum and the posterior capsule of the end of the pancreas. A small enterotomy is then made in the jejunum to match the size of the pancreatic duct and an inner layer of interrupted 5-0 absorbable monofilament sutures is used to create a duct-to-mucosa anastomosis. A short segment of a pediatric feeding tube may be placed across the anastomosis to be used as a temporary indwelling

stent. The anastomosis is completed with an outer layer of 3-0 silk sutures placed between the anterior pancreatic capsule and the jejunum. An alternative to this duct-to-mucosa technique is to create an enterotomy approximately the same size as the pancreatic neck and to complete a running anastomosis circumferentially around the entire gland. This technique then allows invagination of the neck 1 to 2 cm into the lumen of the bowel by the outer anterior layer of the anastomosis. The biliary-enteric anastomosis is performed 10 cm distal to the pancreaticojejunostomy. An end-to-side hepaticojejunostomy is performed with a single interrupted layer of 4-0 absorbable synthetic suture material. No T-tube or stent is generally necessary. Approximately 15 cm distal to the biliary-enteric anastomosis, an end-to-side duodenojejunostomy is performed with an inner continuous layer of 3-0 absorbable synthetic suture material and an outer interrupted layer of 3-0 silk. Alternatively, some experienced pancreatic surgeons perform the duodenal-jejunal anastomosis further distally in an antecolic position, feeling that this technique decreases the incidence of early postoperative delayed gastric emptying. The final reconstruction is shown in Figure 54.6C.

Extent of Resection. Several technical aspects of pancreaticoduodenectomy remain controversial: (a) whether or not a radical lymph node dissection is necessary, (b) whether a pylorus-preserving or classic pancreaticoduodenectomy should be performed, and (c) whether or not there is a role for laparoscopic pancreatic resections.

Several nonrandomized retrospective studies have advocated adding a radical (extended) retroperitoneal lymph node dissection to pancreaticoduodenectomy in an attempt to improve survival. However, results from four randomized prospective trials²⁰⁻²³ (Table 54.10) have shown extended lymph node dissections not to be beneficial. The prospective trial performed by Pedrazzoli et al.²⁰ suggested a survival advantage to extended retroperitoneal lymph node dissection in patients with positive lymph nodes. Eighty-one patients with pancreatic adenocarcinoma were randomized to either standard or radical lymphadenectomy over 3 years at six different institutions. While the two groups were similar with respect to preoperative parameters, operative morbidity, and overall survival, a subgroup analysis of the 48 patients with positive lymph nodes showed a statistically significant survival advantage for patients undergoing the extended lymph node dissection. However, the largest prospective randomized trial from the Johns Hopkins Hospital failed to demonstrate a survival advantage for a radical resection as compared with a classic pancreaticoduodenectomy.²¹ Two hundred and ninety-four patients undergoing resection for periampullary adenocarcinoma were randomized between a standard resection (pylorus-preserving pancreaticoduodenectomy with en bloc resection of the anterior and posterior pancreaticoduodenal lymph nodes, lower hepatoduodenal lymph nodes, and nodes along the right lateral aspect of the superior artery and vein) and a radical resection (standard resection plus distal gastrectomy and retroperitoneal lymph node dissection extending from the right renal hilum to the left lateral border of the aorta and from the portal vein to the inferior mesenteric artery). The groups did not differ with respect to age, gender, site of primary tumor, lymph node status, or margin status. There were no significant differences in 1-, 3-, or 5-year and median survival when comparing the standard and radical groups (Fig. 54.7). However, the radical group had a higher overall morbidity (43% vs. 29%) with significantly higher rates of delayed gastric emptying and pancreatic fistula in addition to a longer postoperative hospital stay.

In 1978, Traverso and Longmire²⁴ popularized the pylorus-preserving modification of the Whipple procedure. Preserving antral and pyloric function, the pylorus-preserving Whipple procedure reduces the incidence of troublesome postgastrectomy symptoms. A number of studies have documented that

Pancreaticoduodenectomy with or without distal gastrectomy and extended retroperitoneal lymphadenectomy for peripapillary adenocarcinoma, part 2: randomized controlled trial evaluating survival, morbidity, and mortality. *Ann Surg* 2002;236:355.)

gastrointestinal function is better preserved in the pylorus-sparing modification than in the traditional operation. In addition, compared with the classic Whipple operation, the pylorus-preserving procedure is less time-consuming and technically easier to perform. Concerns exist in the use of the pylorus-preserving Whipple procedure for the management of peripapillary tumors because of the possibility of compromising the already small proximal surgical margin of resection. This question has been addressed by a number of authors, and no difference appears to be found in survival among those patients treated with the pylorus-sparing Whipple procedure and those managed by the traditional Whipple resection.²⁵⁻²⁷ Therefore, many pancreatic surgeons favor pylorus-preserving pancreaticoduodenectomy because it shortens the operative time, retains the entire stomach as a reservoir, and has a similar survival rate as compared with the classic pancreaticoduodenectomy.

In recent years significant advances have been made in the application of minimally invasive techniques to the management of both benign and malignant pancreatic disorders. Initially, laparoscopic pancreatic surgery was limited to diagnostic staging in patients with pancreatic cancer prior to resection. More recently minimally invasive techniques have been used to manage benign and malignant lesions of the pancreas. While laparoscopic distal pancreatic resections are being performed with increasing frequency,²⁸ the role of laparoscopic pancreaticoduodenectomy (PD) remains controversial. Laparoscopic PD is a technically demanding procedure due to the retroperitoneal location of the pancreas, its intimate association with surrounding gastrointestinal and major vascular structures, and the need for three separate anastomoses to complete the reconstruction. In addition, it is unclear whether an adequate cancer operation can be performed with respect to lymph node harvest and margin status in patients with malignancy. Currently, laparoscopic PD is only performed in a handful of specialized centers. The procedures are performed as either pure laparoscopic, hand assisted or as laparoscopic-assisted procedures with the resection being performed laparoscopically and the reconstruction being completed via a “mini” laparotomy or through a hand port.

Palanivelu et al.²⁹ describe 42 patients who successfully underwent laparoscopic PD for ampullary carcinoma ($n = 24$), pancreatic cystadenocarcinoma ($n = 4$), pancreatic adenocarcinoma ($n = 9$), distal cholangiocarcinoma ($n = 3$), and chronic pancreatitis ($n = 2$). All of the procedures were able to be completed with a totally laparoscopic technique and there were no conversions to open. There was one perioperative mortality (2.4%) and the complication rate was 31%. The operative time averaged 370 minutes and the postoperative length of stay was 10.1 days. All patients underwent an R0 resection

and the mean number of lymph nodes removed in the specimen was 13 (range, 8 to 21). These results are comparable to those of open pancreaticoduodenectomy. The authors emphasize the importance of patient selection in attempting laparoscopic PD. They recommend limiting the procedure to otherwise healthy, nonobese patients with early ampullary or distal bile duct cancers or patients with small (<2 cm) pancreatic cancers with minimal inflammatory changes in the pancreas and no evidence of superior mesenteric vein/portal vein involvement by preoperative imaging. In addition, they state that it should be attempted only after obtaining considerable experience in laparoscopic pancreatic surgery and not simply advanced laparoscopic surgery.

Carcinoma of the Body and Tail

The surgical management of adenocarcinoma of the body and tail of the pancreas is much more limited than that of the head of the pancreas because of the extent of the disease usually present at the time of symptomatic presentation. Most patients are unable to undergo resection, based on findings of major vascular involvement on CT or peritoneal or liver metastases on laparoscopy. If an attempt at open exploration for possible cure is undertaken, the exploration should be started with a search for evidence of either metastatic disease to the liver or peritoneal implants. If this is not the case, the lesser sac is opened, and the SMV is identified as it passes under the neck of the pancreas. If this vessel is normal, and if the splenic vein does not appear to be obstructed preoperatively, a distal pancreatectomy with splenectomy is performed. The spleen is mobilized, as is the distal pancreas, and an en bloc resection of the structure, including the mass, is obtained. The resection should be extended as proximally as possible, with the transected pancreas simply oversewn. The tumor bed should be marked with the placement of clips for postoperative radiation therapy. If, as in most cases, the tumor cannot be resected, a tissue biopsy should be performed, in addition to a chemical splanchnicectomy with alcohol for pain management. In some cases, a prophylactic gastrojejunostomy may be indicated because of the potential for obstruction by tumor at the ligament of Treitz.

Postoperative Results

- 4 During the 1960s and 1970s, many centers reported operative mortality following pancreaticoduodenectomy in the range of 20% to 40%, with postoperative morbidity rates as high as 40% to 60%. During the last two decades, a dramatic decline

in operative morbidity and mortality following pancreaticoduodenectomy has been reported at a number of centers, with operative mortality rates in the range of 2% to 5%.^{30–32} The reasons behind this decline appear to be the following: (a) fewer, more experienced surgeons are performing the operation on a more frequent basis; (b) preoperative and postoperative care has improved; (c) anesthetic management has improved; and (d) large numbers of patients are being treated at high-volume centers.³³

Although the operative mortality rates for pancreatic cancer have been reduced significantly, the complication rates approach 40% (Table 54.11). Pancreatic fistula remains the most frequent serious complication following pancreaticoduodenectomy, with an incidence ranging from 5% to 15%. In the past, the development of pancreatic fistula after pancreaticoduodenectomy was associated with mortality rates of 10% to 40%. Although the incidence of pancreatic fistula following pancreaticoduodenectomy remains stable, the overall associated mortality rate has diminished owing to improved management. Important supportive measures include careful maintenance of fluid and electrolyte balance, parenteral nutrition, and controlling the pancreatic leak with percutaneous or intraoperative drainage.

Long-term Survival

Historically, 5-year survival rates for patients undergoing resection for adenocarcinoma of the head of the pancreas were reported to be in the range of 5%. However, recent studies have suggested an improved survival for patients following pancreaticoduodenectomy. In 2006, Winter et al.³⁴ reported on 1,175 patients with cancer of the pancreas managed by resection. The

actuarial 5-year survival for these patients was 18%, with a median survival of 18 months (Fig. 54.8). In this study, factors found to be important predictors of survival included tumor diameter (<3 cm), negative resection margin status, well/moderate tumor differentiation, and postoperative chemoradiation treatment. Patients who underwent resection with negative margins had a median survival of 20 months and a 5-year survival of 21%, whereas those with positive margins fared significantly worse, with a median survival of 14 months and a 5-year survival of 12%. The outcome was particularly favorable in the subgroup of patients with small tumors (<3 cm) who underwent margin-negative, node-negative resections; the median survival was 44 months and the 5-year survival was 43%.

ADJUVANT AND NEOADJUVANT THERAPY

At present, the general consensus of most surgeons treating patients with pancreatic carcinoma is that any future improvement in survival for this disease will involve improvements in adjuvant therapy. Despite advances in surgery and perioperative care that have resulted in markedly reduced postoperative mortality after pancreaticoduodenectomy, the median survival for pancreatic cancer patients has changed minimally over the past two decades. Even with optimal surgical management, 5-year survival averages 15% to 20% for resectable disease and 3% for all stages combined. Approximately 85% of patients with resected pancreatic cancer will ultimately have a recurrence and die of their disease. This suggests that in most cases pancreatic cancer is a systemic disease at the time of diagnosis, making surgical resection alone inadequate therapy. The results of the most important randomized prospective trials of adjuvant therapy for pancreatic cancer are summarized in Table 54.12.

6 In 1985, the Gastrointestinal Tumor Study Group (GITSG) reported encouraging results from a prospective randomized trial to evaluate the efficacy of adjuvant radiation and chemotherapy following curative resection for adenocarcinoma of the head of the pancreas.³⁵ Forty-three patients were randomized to either adjuvant therapy with radiation and 5-fluorouracil (5-FU) or no adjuvant therapy. The median survival for the 21 patients who received adjuvant therapy was 20 months, and three (14%) survived 5 years or longer. For the 22 patients who received no adjuvant therapy, the median survival was 11 months, and only one patient (4.5%) survived 5 years.

The randomized trial conducted by the European Organization for Research and Treatment of Cancer (EORTC)³⁶ sought to recapitulate the results of the GITSG study in 114 patients with pancreatic head lesions (observation, $n = 54$; adjuvant treatment, $n = 60$). However, chemotherapy (5-FU) given during radiation was given as a continuous infusion (rather than via bolus) during each radiation sequence, depending on toxicity, for up to 5 days. No chemotherapy was given postchemoradiation. Fifty-six percent of patients received the intended chemotherapy dose during radiation. Patients in the chemoradiation arm had a median survival of 17.1 months versus 12.6 months in the observation arm ($p = 0.099$); 2- and 5-year overall survivals were 37% and 20%, respectively, for the experimental arm and 23% and 10%, respectively, for the control arm.

The European Study Group for Pancreatic Cancer (ESPAC-1) trial published in 2004 analyzed 289 patients recruited from 53 hospitals in a 2×2 factorial design.³⁷ The four study groups included (a) surgery only ($n = 69$); (2) chemotherapy only ($n = 73$) consisting of 5-FU, 425 mg/m², and leucovorin, 20 mg/m², given daily for 5 days every 4 weeks for six cycles of treatment; (c) radiation therapy and 5-FU given ($n = 75$) according to the

5-FU, 5-fluorouracil; EORTC, European Organization for Research and Treatment of Cancer; ESPAC, European Study Group for Pancreatic Cancer; GITSG, Gastrointestinal Tumor Study Group; Surg, surgical; ROTC, Radiation Therapy Oncology Group; XRT, radiation therapy.

original GITSG method; and (d) both treatments ($n = 73$, chemoradiation followed by chemotherapy). The major study conclusions were the 5-year overall survival comparisons between patients who received chemotherapy versus those who did not (21% vs. 8%, $p = 0.009$) and those who received radiation therapy versus those who did not (10% vs. 20%, $p = 0.05$). The authors concluded that adjuvant chemotherapy had a beneficial effect in resected pancreas cancer, whereas chemoradiation had a deleterious effect. A quality-of-life questionnaire showed no difference between those who received chemotherapy and those who did not and those who received chemoradiation and those who did not. Thus, the survival benefit of adjuvant chemoradiation for pancreatic cancer patients remains unclear, and the optimal regimen has yet to be determined.

The Radiation Therapy Oncology Group (RTOG) 9704 trial, presented in abstract form in 2006,³⁸ contained 442 eligible patients who received adjuvant chemoradiation (5,040 cGy) given as continuous fractions with radiosensitizing doses of 5-FU. The comparisons were with the addition of either three cycles of 5-FU (one prechemoradiation, two postchemoradiation for 12 weeks) or four cycles of gemcitabine (one prechemoradiation, three postchemoradiation). Although the study showed no overall difference in aggregate survival, when pancreatic head

lesions only were considered (eliminating study results from resected lesions in the pancreatic body or tail), both median survival (16.7 vs. 18.8 months) and overall survival at 3 years (21% vs. 31%) favored the gemcitabine arm ($p = 0.047$). The study concluded that the addition of adjuvant gemcitabine to postoperative 5-FU chemoradiation was superior to the addition of 5-FU.

The CONKO-1 trial,³⁹ conducted in Germany and Austria, represented a randomization of 368 patients following R0 or R1 resection to either observation or an experimental arm of gemcitabine. After a median follow-up time of 53 months, the median disease-free survival was 13.9 months in the gemcitabine arm versus 6.9 months in the observation arm ($p < 0.001$). There was no difference in overall survival for the gemcitabine arm versus the control group—median survival was 22 versus 20 months. Although survival was not different, the authors concluded that postoperative gemcitabine significantly delayed the development of recurrent disease after complete resection of pancreatic cancer compared with observation alone and, thus, was supported as adjuvant therapy in resectable pancreatic cancer.

At present, many centers are utilizing preoperative neoadjuvant chemoradiation for the treatment of pancreatic cancer (Table 54.13). Neoadjuvant therapy offers several

TABLE 54.13

TREATMENT

SELECTED NEOADJUVANT TRIALS FOR POTENTIALLY RESECTABLE PANCREATIC CANCER

AUTHOR	YEAR	n	REGIMEN	RESECTED (%)	MEDIAN SURVIVAL (mo)
Spitz et al. ⁴⁰	1997	91	XRT, 5-FU	45	19
Hoffman et al. ⁴¹	1998	53	XRT, 5-FU, Mitomycin C	45	16
Pisters et al. ⁴²	2002	37	XRT, Paclitaxel	54	19
Wolff et al. ⁴³	2002	86	XRT, Gemcitabine	73	36

5-FU, 5-fluorouracil; XRT, radiation therapy.

potential benefits, including (a) delivery of treatment to well-oxygenated tissue, which enhances efficacy of chemoradiation; (b) downstaging, which can enhance ability to achieve a negative margin resection and thereby reduce local recurrence; and (c) avoidance of surgery in patients with rapidly progressive disease. Neoadjuvant therapy can be completed without increasing the subsequent morbidity and mortality of surgical resection. The group from the M.D. Anderson Cancer Center has reported on the multimodality treatment of 142 consecutive patients with localized adenocarcinoma of the pancreatic head.⁴⁰ A subset of 41 patients treated by preoperative chemoradiation and pancreaticoduodenectomy were compared with 19 patients receiving pancreaticoduodenectomy and postoperative adjuvant chemoradiation. Surgery was not delayed for any patient who received preoperative chemoradiation because of chemoradiation toxicity, but 24% of the eligible patients did not receive their intended postoperative chemoradiation because of delayed recovery following pancreaticoduodenectomy. The patients treated with rapid fractionation were reported to have a significantly shorter duration of treatment (median, 62.5 days) than patients who received postoperative chemoradiation (median, 98.5 days). In early follow-up, no patient who received preoperative chemoradiation experienced a local recurrence, and peritoneal recurrence developed in only 10% of these patients. Local or regional recurrence developed in 21% of patients who received postoperative chemoradiation. The overall survival curves were similar for both cohorts.

Wolff et al.⁴³ examined 86 patients treated with weekly gemcitabine at a dose of 400 mg/m² and 30 Gy of radiation. Sixty-one patients ultimately underwent resection (71%). The median survival in the resected patients was 36 months, which is significantly longer than those seen in regimens using 5-FU or paclitaxel as the radiation sensitizer. Analysis of the specimens revealed two pathologic complete responses and more than 50% nonviable tumor cells in 36 (59%). A gemcitabine-based regimen was also used in a multi-institutional study of 20 patients reported by Talamonti et al.⁴⁴ This group used full-dose gemcitabine and limited-field radiation to 36 Gy (2.4 Gy/fraction). The authors described 14 patients as resectable and six as borderline resectable. Ultimately, all patients were explored and 17 resected (85%), again representing a very high rate of resectability. A single pathologic complete response was observed and, in 24% of tumors, greater than 90% of the tumor cells were felt to be nonviable. Also notable was the low incidence, 6%, of margin positivity in this trial. The median survival in the resected patients was 26 months. Based on the results of these initial trials, gemcitabine-based neoadjuvant regimens remain of considerable interest.

PALLIATION

- 7 Unfortunately, it has been the experience nationwide that only a minority of patients with carcinoma of the pancreas can undergo resection for possible cure at the time diagnosis is made. Therefore, the optimal palliation of symptoms to maximize quality of life is of primary importance in most patients with pancreatic cancer. Both operative and nonoperative options are available for the palliation of pancreatic cancer.

Jaundice

Obstructive jaundice is present in most patients who have pancreatic cancer. If left untreated, it can result in progressive liver dysfunction, hepatic failure, and early death. In addition,

the pruritus associated with obstructive jaundice can be debilitating and usually does not respond to medication. When patients undergo exploration for possible cure and are found to have unresectable disease, a biliary bypass should be performed.

Traditionally, surgeons have performed either choledochojejunostomy or cholecystojejunostomy for the relief of malignant biliary obstruction. Both procedures are effective in relieving jaundice, but it appears that the rate of recurrent jaundice after cholecystojejunostomy is approximately 10%. Therefore, our preference for the palliation of obstructive jaundice is a hepaticojejunostomy or choledochojejunostomy reconstructed with a Roux-en-Y limb of jejunum. The surgical palliation of jaundice can be accomplished safely, with a mortality rate of less than 3% and an overall morbidity rate of 30% to 40%.⁴⁵ In recent years, nonoperative palliation has become available as an option for managing patients who are deemed unresectable by preoperative staging. Plastic or metal stents can be placed across the biliary obstruction by either an endoscopic or a percutaneous technique. For pancreatic cancer, the endoscopic approach is usually preferred. The overall morbidity rate for endoscopic stenting ranges up to 35%, but the rate of major procedure-related morbidity is less than 10%. Early complications include cholangitis, pancreatitis, and bile duct or duodenal perforation. The major late complications of stent placement are cholecystitis, duodenal perforation, and stent migration. Stent occlusion can result in episodes of cholangitis and recurrent jaundice. For most patients, an exchange of stents is required every 3 to 6 months. The newer metal stents appear to remain patent for longer periods.

Nonoperative palliation appears to be associated with lower complication rates, lower procedure-related mortality rates, and shorter initial periods of hospitalization in comparison with surgical palliation. However, the rate of recurrent jaundice is higher. No advantage with respect to long-term survival has been noted for either approach. Therefore, nonoperative palliation should be offered to patients with advanced disease or poor performance status. Surgical palliation should be considered for patients with an anticipated life expectancy of at least 6 months.

Duodenal Obstruction

At the time that pancreatic cancer is diagnosed, approximately one third of patients have symptoms of nausea or vomiting. Although true mechanical obstruction of the duodenum seen by radiologic or endoscopic examination is much less frequent, duodenal obstruction develops in almost 20% of patients before they die as the disease progresses.⁴⁶ Duodenal obstruction can be caused in the C-loop by cancers of the head or at the ligament of Treitz by cancers of the body and tail. In patients with evidence of duodenal obstruction or impending obstruction, a gastrojejunostomy is indicated for palliation. This is typically performed as a retrocolic, isoperistaltic loop gastrojejunostomy with a loop of jejunum 20 to 30 cm distal to the ligament of Treitz.

In patients with unresectable pancreatic cancer who do not have symptoms of gastric outlet obstruction, whether or not to perform a prophylactic gastric bypass at the time of biliary bypass is a matter of debate. Surgeons who do not perform a prophylactic bypass feel that it needlessly increases the postoperative length of stay and can be associated with delayed gastric emptying and increased morbidity and mortality. However, data from a prospective randomized trial of prophylactic gastrojejunostomy in patients with unresectable cancer do not support this view.⁴⁷ In this study, 44 patients were randomized to a gastrojejunostomy, and 43 did not undergo gastric bypass. No mortality occurred in either group. No difference was observed in either the

TABLE 54.14

MANAGEMENT

PROSPECTIVE RANDOMIZED TRIAL OF PROPHYLACTIC GASTROJEJUNOSTOMY IN PATIENTS WITH UNRESECTABLE PERIAMPULLARY CANCER

	■ PATIENTS (no.)	■ MORBIDITY (%)	■ MORTALITY (%)	■ POSTOPERATIVE LENGTH OF STAY (d)	■ LATE GASTRIC OUTLET OBSTRUCTION (%)
Gastrojejunostomy	44	32	0	8.5	0
No gastrojejunostomy	43	33	0	8.0	19

complication rate or the postoperative length of stay (Table 54.14). However, late duodenal obstruction developed in 19% of the patients who did not undergo bypass. A recent multicenter prospective randomized controlled trial has confirmed these results.⁴⁸ Therefore, we believe that a prophylactic gastrojejunostomy should be performed in patients undergoing surgical palliation for unresectable pancreatic carcinoma.

Pain

Tumor-associated pain can be incapacitating in patients with unresectable pancreatic cancer. The postulated causes of tumor-associated pain are many and include tumor infiltration into the celiac plexus, increased parenchymal pressure caused by pancreatic duct obstruction, pancreatic inflammation, gallbladder distention resulting from biliary obstruction, and gastroduodenal obstruction. The management of pain in patients dying of carcinoma of the pancreas is one of the most important aspects of their care. The appropriate use of oral agents can be successful in most patients. Patients with significant pain should receive their medication on a regular schedule and not an “as needed” basis. The use of long-acting morphine derivative compounds appears to be best suited for such treatment. Percutaneous neurolytic block of the celiac axis, performed under either fluoroscopic or CT guidance, is also successful in the majority of patients at eliminating pain. Patients with unresectable cancer at the time of surgical exploration should receive a chemical splanchnicectomy, with 20 mL of 50% alcohol injected on either side of the aorta at the level of the celiac axis.⁴⁹

Summary

The decision to perform nonoperative versus surgical palliation for pancreatic cancer is influenced by a number of factors, including the patient's symptoms, overall health status, predicted procedure-related morbidity and mortality, and projected survival. Surgical palliation can be completed with acceptable perioperative morbidity and mortality and postoperative length of stay. The avoidance of late complications of recurrent jaundice, duodenal obstruction, and disabling pain would strengthen the argument in favor of surgical palliation in those patients expected to survive 6 months or more. Nonoperative methods of palliation should be considered for patients in whom preoperative staging suggests distant metastatic disease or a locally unresectable tumor, patients who are not candidates for operative intervention, and those not expected to survive more than 3 months.

Radiation and Chemotherapy for Unresectable Pancreatic Carcinoma

Specific antitumor therapies in patients with advanced pancreatic carcinoma have been studied for years, with limited success. Trials evaluating the use of chemotherapy and radiation therapy both alone and in combination have shown a marginal improvement in survival, often with relatively high toxicity rates and some negative impact on quality of life. Recently gemcitabine, a deoxycytidine analogue capable of inhibiting DNA replication and repair, has become increasingly popular. When gemcitabine was compared with bolus 5-FU in a randomized phase III trial, it was shown to confer a significant survival benefit in advanced pancreatic cancer, increasing median survival from 4.4 months to 5.7 months and increasing 1-year survival from 2% to 18%, respectively.⁵⁰ A key endpoint in this study was “clinical benefit response,” based on reducing pain, improving performance status, and inducing weight gain, which was attained in 24% of patients receiving gemcitabine compared with 5% for those receiving 5-FU. In patients with metastatic pancreatic cancer that had progressed with 5-FU and then been treated with gemcitabine, the median survival (in 63 of 74 patients enrolled) was 3.9 months.⁵¹ Seventeen patients (27%) attained a clinical benefit response with a median duration of 14 weeks. Gemcitabine is generally well tolerated with a low incidence of significant toxicity and therefore seems to be a reasonable choice for palliative therapy.

In addition to gemcitabine, other agents are currently being studied for a role in the palliation of patients with pancreatic adenocarcinoma. Examples of such agents are paclitaxel (Taxol), matrix metalloproteinase inhibitors (e.g., marimastat, perillyl alcohol), and inhibitors of angiogenesis, such as TNP-470. The results of such studies are eagerly awaited.

CHAPTER 55 ■ NEOPLASMS OF THE ENDOCRINE PANCREAS

EUGENE P. KENNEDY, JONATHAN R. BRODY, AND CHARLES J. YEO

KEY POINTS

- 1 Pancreatic endocrine neoplasms (PENs) originate from multipotential stem cells in pancreatic ductules. Therefore, use of the older terms *islet cell tumor* and *islet cell carcinoma* is now discouraged, in favor of the terms *pancreatic endocrine neoplasms* or *pancreatic endocrine tumors*.
- 2 PENs are best classified according to the size and the mitotic rate of the tumor into one of three categories: pancreatic endocrine microadenomas, well-differentiated pancreatic endocrine neoplasms, and poorly differentiated or high-grade endocrine carcinomas.
- 3 The World Health Organization classification divides well-differentiated PENs into well-differentiated endocrine tumors and well-differentiated endocrine carcinomas based on local invasion beyond the pancreas or metastatic spread to lymph nodes and/or distant locations, which results in classification as carcinoma.
- 4 The best initial imaging technique for a pancreatic endocrine neoplasm is a high-quality multidetector computed tomography scan.
- 5 Endoscopic ultrasonography is particularly useful in localizing tumors in patients with gastrinoma and insulinoma.
- 6 Insulinomas may present with either neuroglycopenic symptoms (confusion, seizure, obtundation, coma) or hypoglycemic-induced symptoms (palpitations, diaphoresis, tachycardia).
- 7 Ninety percent of insulinomas are solitary, 90% are sporadic, and 90% are benign with location evenly distributed throughout the pancreas.
- 8 Seventy-five percent of gastrinomas are sporadic (25% are associated with multiple endocrine neoplasia type 1 syndrome), and all should be considered to be of malignant potential.
- 9 Most gastrinomas are located in the *gastrinoma triangle* and may be intrapancreatic, within the wall of the duodenum, or in a peripancreatic lymph node, and in most cases local resection (enucleation) may be adequate therapy.
- 10 Glucagonomas usually present with a characteristic severe dermatitis (termed *neurolytic migratory erythema*) and are typically large and bulky and often with metastatic disease.

Pancreatic endocrine neoplasms (PENs) are rare tumors that account for 1% to 2% of pancreatic neoplasms.¹ First described by Nicholls in 1902 as a tumor arising from pancreatic islet cells, these “islet cell adenomas” were long thought to arise from the islets of Langerhans.² Recent investigations have revealed that PENs more likely originate from multipotential stem cells in pancreatic ductules.^{3,4} This non-islet cell origin has been further demonstrated in tumors arising in patients with multiple endocrine neoplasia type 1.⁵ Therefore, use of the older terms *islet cell tumor* and *islet cell carcinoma* is now discouraged, in favor of the terms *pancreatic endocrine neoplasms* or *pancreatic endocrine tumors*.^{6,7}

- 2 Overall, PENs are best classified according to the size and the mitotic rate of the tumor (Table 55.1). This system places PENs into one of three categories: pancreatic endocrine microadenomas, well-differentiated pancreatic endocrine neoplasms, and poorly differentiated or high-grade endocrine carcinomas. Additionally, they can be classified by the presence (i.e., functional tumors) or absence (i.e., nonfunctional tumors) of a syndrome due to hormone production. The production of certain hormones and the resulting syndromes lead to well-described clinical syndromes, which are detailed later in this chapter.

PENs less than 0.5 cm in diameter are classified as pancreatic endocrine microadenomas. Oncologically, they are considered to be benign lesions. Their prevalence is estimated to be as high as 10% of the population in autopsy series.^{8,9} Most pancreatic endocrine microadenomas are noted as incidental findings in pancreata resected for other indications and, by definition, produce no neoplastic syndromes (i.e., are nonfunctional). Functional PENs less than 0.5 cm are classified with well-differentiated pancreatic endocrine neoplasms.

PENs measuring greater than 0.5 cm in diameter and having a low mitotic rate of less than 10 mitoses per 10 high-power fields are referred to as well-differentiated pancreatic endocrine neoplasms. This group comprises the large majority of clinically relevant PENs. They are uncommon, with an estimated incidence of approximately 1 out of 100,000 people.^{10,11} Although rare in children, cases have been described at all ages, and the peak incidence occurs between the ages of 40 and 60 years.⁶ Overall distribution is equal between men and women with some differences in ratio among different functional types.

No well-established staging system exists for PENs.¹² Multiple studies have been performed attempting to establish prognostic characteristics such as size, mitotic count, vascular and perineural invasion, nuclear polymorphisms, and Ki-67 labeling index.^{13–16} The most recent World Health Organization (WHO) classification divides well-differentiated PENs into well-differentiated endocrine tumors and well-differentiated endocrine carcinomas based on their clinical behavior.¹ Any local invasion beyond the pancreas or metastatic spread to lymph nodes or distant locations results in classification as carcinoma. The WHO well-differentiated endocrine tumors are further subclassified as having predicted benign behavior or uncertain behavior. This subdivision (benign vs. uncertain) is based on size (<2 cm or ≥2 cm), mitotic count (less than two or two or more mitotic figures per 10 high-power fields), Ki-67 labeling index (<2% or ≥2%), and absence or presence of perineural and vascular invasion (Table 55.2).

Well-differentiated PENs can also be classified as functional or nonfunctional based on the presence or absence of an associated clinically recognizable syndrome (Table 55.3). These syndromes are the result of the secretion of biologically active

TABLE 55.1

CLASSIFICATION

CLASSIFICATION OF PANCREATIC ENDOCRINE NEOPLASMS

■ NEOPLASM	■ SIZE	■ MITOTIC RATE	■ CLINICAL BEHAVIOR
Pancreatic endocrine microadenomas	<0.5 cm	<2 per 10 HPF	Benign
Well-differentiated pancreatic endocrine neoplasms	>0.5 cm	<10 per 10 HPF	Indeterminate
High-grade endocrine carcinomas	Any	>10 per 10 HPF	Malignant

HPF, high-power fields.

hormones by the tumors and are confirmed by measurable elevations of the hormones in the blood. The most common functional PENs include insulinomas, gastrinomas, vasoactive intestinal polypeptide-omas (VIPomas), glucagonomas, and somatostatinomas. The incidence of these lesions ranges from 1 per 1 million for insulinomas to 1 per 40 million for somatostatinomas.¹⁷ Even less common PENs secreting calcitonin,^{18,19} parathyroid hormone-related protein,²⁰ growth hormone-releasing factor, and adrenocorticotrophic hormone²¹ have been reported. Nonfunctional PENs are classified as such due to their lack of an associated clinical syndrome. Some of the tumors in this group do secrete elevated amounts of hormones, including chromogranin A, which can be detected in either the serum or surgical specimens using immunohistochemistry.²² These secreted hormones either produce no clinical syndromes, as is seen with tumors that secrete pancreatic polypeptide,²³ or secrete hormones in subclinical amounts or inactive forms. Traditionally, functional PENs were reported to comprise the majority of PENs. As methods of detecting these lesions and patterns of presentation have evolved, due primarily to the widespread use of high-quality cross-sectional imaging, nonfunctional PENs now comprise more than half of surgically resected cases.^{13,24}

The least common group of PENs is the poorly differentiated or high-grade endocrine carcinomas. These are aggressive tumors characterized by their high mitotic count (>10 mitotic figures per 10 high-powered fields).²⁵ These tumors primarily occur in adults and have a male predominance. Some have been reported to be functional, producing varied clinical syndromes (commonly gastrinoma, VIPoma, glucagonoma, and, less frequently, insulinoma). Prognosis is often poor, with the clinical course varying from a rapid decline to a more indolent, prolonged survival.

MOLECULAR GENETICS

The majority of PENs are sporadic. Some of them, however, occur as part of inherited familial syndromes such as multiple endocrine neoplasia type 1 (MEN-1), von Hippel-Lindau (VHL) syndrome, neurofibromatosis (NF-1), and tuberous sclerosis (TSC) (Table 55.4). Recent technical advances in

molecular biology have provided new insights into the genesis of PENs and possible reasons why certain tumors behave more aggressively than others. Further, recent studies analyzing the gross chromosomal changes found in PENs provide hope for markers for early diagnosis of this disease.

Familial Syndromes

Significant progress has been made in the genetic understanding of the MEN-1 syndrome in relation to PENs.²⁶ Chromosomal linkage studies have localized the genetic defect to the 11q13 locus, and studies of DNA markers have localized the MEN-1 gene between PYGM and D11S97. The gene contains 10 exons that code for a 610-amino-acid protein called menin, whose function is unknown, although it is classically labeled as a tumor suppressor gene. Some studies provide a possible explanation for loss of this gene in neuroendocrine tumors.²⁷ The menin protein is expressed in diverse tissues and is highly conserved evolutionarily. Menin is predominately a nuclear protein, which binds to JunD and may repress JunD-mediated transcription. Studies in patients with MEN-1 have shown allelic deletions at chromosome 11q13 in nearly 100% of parathyroid tumors, 85% of nongastrinoma islet cell tumors, and up to 40% of gastrinomas. In patients with sporadic tumors (without MEN-1), 11q13 deletions are seen in about 25%, 20%, and almost 50% of parathyroid tumors, nongastrinoma PENs, and gastrinomas, respectively. Recently it has been shown that a comprehensive genetic testing program for patients at risk for MEN-1 can identify patients harboring a MEN-1 mutation almost 10 years before the development of clinical signs or symptoms of disease.²⁸ Since MEN-1 loss has been detected in both the sporadic and the familial forms of PENs, the menin pathway is most likely involved in the pathogenesis of this disease.²⁷

Less frequently than MEN-1, PENs may be associated with VHL syndrome. VHL syndrome is another autosomal dominant inheritance disease that includes many clinical disorders,²⁹ including retinal hemangioblastomas, cerebellar and medullary hemangioblastomas, and PENs. PENs are found in a small percentage of patients with VHL syndrome. A mutation in the VHL gene, a tumor suppressor located on chromosome 3p25–26,

Somatostatinoma	Hyperglycemia Steatorrhea Gallstones	Rare	Most

WDHA, watery diarrhea, hypokalemia, and either achlorhydria or acidosis.

which regulates hypoxia-induced cell proliferation, is responsible. Although germline mutations with loss of heterozygosity (LOH) are associated with this disease, it has been proposed that other tumor suppressors most likely cooperate with VHL in order to form PENs.

NF-1 (von Recklinghausen disease) is an autosomal dominant disorder that produces a well-described clinical syndrome characterized by café-au-lait spots and neurofibromas. These patients may develop pancreatic somatostatinomas. The NF-1 gene is a tumor suppressor gene located on 17q11.2 that encodes for neurofibromin, a regulator of the mammalian target of rapamycin (mTOR) pathway. Loss of NF-1 results in mTOR activation and tumor development.³⁰

Sporadic Pancreatic Endocrine Neoplasms

The genetic landscape of sporadic PENs has been explored. Up to half of malignant pancreatic endocrine tumors have been found to have clonal chromosomal abnormalities,³¹ whereas, unlike with pancreatic ductal adenocarcinoma, k-ras oncogene mutations are absent in most of these tumors.³² Gastrinoma has been shown to be associated with amplification of the HER2/neu proto-oncogene,³³ and a high level of expression of

mRNA for the α subunit of G_s protein has been demonstrated in insulinoma.³⁴ MAGE1, a protein identified in a number of neoplastic cell types including testicular germ cell cancer, breast cancer, and melanoma, was found to be present in 86% of primary PENs as well as in lymph node metastases.

Additional recent discoveries have furthered our understanding of this diverse group of tumors. For instance, hypermethylation of hMLH1 in PENs leads to microsatellite instability and is associated with an improved prognosis.³⁵ However, the most promising and breakthrough work comes from two studies looking at genome-wide alterations in PENs.^{36,37} Nagano et al.³⁷ found allelic imbalances by utilizing high-density single-nucleotide polymorphism (SNP) arrays. In short, they found that tumors with high allelic imbalances (more than four chromosomal aberrations) had a larger tumor size compared to PENs with minimal chromosomal aberrations ($p = 0.03$). The authors do point to the limitations in the number of tumors (15 patients) analyzed in the study and note the gross heterogeneity found in their samples.

Another intriguing study was performed by Jonker et al.,³⁶ which correlated the following molecular markers with clinical outcomes of PENs (stratifying insulinomas and noninsulinomas): Ki67, CK19, specific chromosomal alterations, gross chromosomal instability (CIN), and tumor size.³⁶ The authors

TABLE 55.4

ETIOLOGY

FAMILIAL GENETIC SYNDROMES ASSOCIATED WITH PANCREATIC ENDOCRINE NEOPLASMS (PENs)

■ SYNDROME	■ CHROMOSOMAL LOCATION	■ GENE PRODUCT	■ PEN TYPE

found a strong correlation between CIN, specific chromosomal alterations, and metastatic disease and poor tumor-free survival in insulinomas and noninsulinomas. The authors also note that CK19 is a strong indicator of tumor-specific death in all PENs.³⁶ Other epigenetic studies have correlated altered methylation patterns in well-characterized tumor suppressor genes (e.g., APC, E-cadherin, p16) with tumor staging.³⁸ Further, Chan et al. assessed differences between methylation patterns in a similar set of genes between carcinoid and pancreatic endocrine tumors. This study found distinct differences between these uncommon tumor types.³⁹

In summary, PENs are most likely difficult to characterize molecularly (and clinically) due to molecular and thus cellular heterogeneity within the tumor. Ongoing efforts to search for candidate genes that lay the foundation for CIN in these tumors will aid in unraveling the molecular etiology of this disease. It was suggested in one study that FANCD2 is a good candidate gene since it resides in a chromosomal region of loss for PENs (chromosome 3p25).^{36,40} However, it should be noted that loss of FANCD2 has been shown previously to be lethal (i.e., counterproductive) to cancer cells.⁴¹ Further studies are needed to explore the connection between the FANCD2 gene and PENs. Currently, using modern techniques such as comparative genomic hybridization (CGH) along with tumor sizing and markers such as CK19 may provide clinically relevant information.

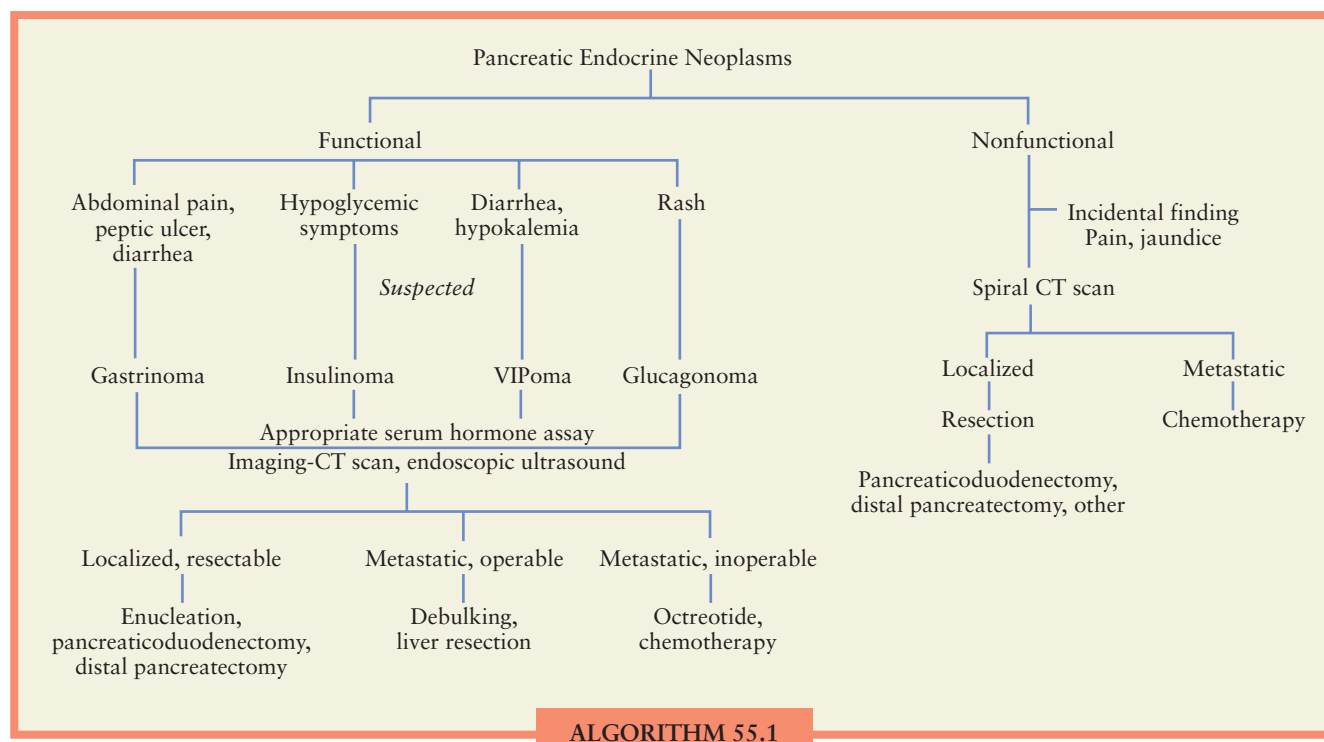

PRESENTATION AND EVALUATION

There are three primary ways by which patients with PENs come to clinical attention: the incidental discovery of a mass in the pancreas during cross-sectional imaging, symptoms secondary to the mass effect of a lesion in the pancreas (i.e., obstructive jaundice or pain), and, as a consequence of the symptoms of, a syndrome associated with a functional PEN. As

mentioned previously, incidentally detected nonfunctional PENs currently comprise the majority of clinically relevant tumors. They are typically hypervascular on imaging studies such as computed tomography (CT) or magnetic resonance imaging (MRI). In the absence of any clinical syndrome, these lesions can be managed as any other incidental pancreatic lesion. Typically, the size of a PEN at discovery guides decision making between three standard options: serial observation, endoscopic ultrasound-guided biopsy, or definitive surgical resection. Size greater than 2 cm is a standard stratification measure, with lesions larger than this usually managed in a more aggressive fashion. If a nonfunctional PEN is suspected, baseline serum levels of chromogranin A and pancreatic polypeptide can be useful diagnostic markers prior to surgical resection.

PENs presenting due to mass effect on surrounding structures resulting in jaundice, pain, or gastric outlet obstruction are uncommon. These lesions should be addressed as any other symptomatic pancreatic lesion with definitive surgical resection if clinically appropriate.

Patients presenting with symptoms from a functional PEN can be a diagnostic challenge. Three general principles apply to the diagnosis and treatment of patients with suspected functional neoplasms of the endocrine pancreas. One must first recognize the abnormal physiology or characteristic syndrome. Patients are often misdiagnosed or have their symptoms disregarded for years before an accurate diagnosis is reached. Characteristic clinical syndromes are well described for insulinoma, gastrinoma, VIPoma, and glucagonoma. The somatostatinoma syndrome is nonspecific, much more difficult to recognize, and exceedingly rare. Second is the detection of hormone elevations in the serum by radioimmunoassay. Such assays are readily available for measuring insulin, gastrin, vasoactive intestinal peptide (VIP), and glucagon. Assays for somatostatin, pancreatic polypeptide (PP), prostaglandins, and other hormonal markers are less commonly available but can be obtained from certain laboratories. The third step involves localizing and staging the tumor in preparation for possible operative intervention (Algorithm 55.1).

ALGORITHM 55.1. Diagnosis and management of pancreatic endocrine neoplasms.

FIGURE 55.1. Computed tomography with oral and intravenous contrast in a patient with biochemical evidence of insulinoma. The neoplasm (arrow) is seen as a contrast-enhancing structure, 3 cm in diameter, in the tail of the pancreas posterior to the stomach (S). (From Yeo CJ. Islet cell tumors of the pancreas. In: Niederhuber JE, ed. *Current Therapy in Oncology*. St. Louis, MO: Mosby; 1993:272, with permission.)

FIGURE 55.2. Octreotide scan (anterior view) in a patient with a large endocrine tumor in the tail of the pancreas (large dark mass, upper right) and several hepatic metastases (upper left quadrant). A small amount of the tracer is seen in the bladder (lower midline).

LOCALIZATION AND STAGING

Computed Tomography

- 4 The initial imaging technique used to localize a PEN and stage the disease is high-quality multidetector three-dimensional CT.⁴² The accuracy of CT in detecting primary pancreatic endocrine neoplasms ranges from 64% to 82% and depends largely on the size of the tumor.^{43,44} PENs are typically hyperdense on arterial phases of imaging. Lesions that are obvious during the early arterial phase can become isodense on later phases of imaging. Therefore, a multiphase approach is typically recommended.^{45,46} CT is useful in assessing size and location of the primary tumor, proximity to visceral vessels, peripancreatic lymph node involvement, and the presence or absence of liver metastases (Fig. 55.1).

Magnetic Resonance Imaging

MRI is increasingly used in the detection of PENs, particularly small lesions. They are especially well visualized on T1- and T2-weighted images with fat suppression. MRI has the advantage of increased soft tissue contrast without the administration of intravenous contrast when compared to CT.⁴² PENs characteristically have high signal intensity on T2-weighted images.⁴⁷ On dynamic contrast-enhanced T1-weighted images, the tumors show the same typical enhancement pattern as on CT scan. The sensitivity of MRI has been reported to be between 74% and 100%.^{43,44}

Somatostatin Receptor Scintigraphy (Octreoscan)

Somatostatin receptor scintigraphy (SRS) also plays an important role in imaging patients with pancreatic endocrine tumors.^{48–54} In this technique, the octapeptide analogue of somatostatin (Octreotide) labeled with indium-111 is adminis-

tered intravenously to patients in whom a PEN is suspected. Because neuroendocrine tumors often express large numbers of somatostatin receptors on their cell surfaces (Fig. 55.2), the tracer preferentially identifies tumors. The overall sensitivity of SRS has been reported to range from 74% to near 100% depending on the functional type of PEN.⁵⁵ There is a significant false-negative rate, indicating that negative SRS findings in patients with pancreatic endocrine neoplasms should be viewed with caution. Nonfunctional tumors and insulinomas seem to be localized less frequently by SRS, while SRS performs well for gastrinoma, VIPoma, and glucagonoma. In addition, SRS appears to play a role in the evaluation of patients with metastatic pancreatic endocrine tumors, especially in identifying extrahepatic tumor spread. In a study by Frilling et al.,⁵⁴ 54% of patients with liver metastases had extrahepatic tumor spread detected by SRS that was not detected by alternate imaging techniques.

Endoscopic Ultrasound

- 5 Endoscopic ultrasonography (EUS) has also shown utility in localizing pancreatic endocrine neoplasms.^{56–60} Rosch et al.⁵⁹ were able to localize 32 of 39 tumors (82%) correctly with EUS after CT had failed to locate the tumor (Fig. 55.3). In their experience, EUS was more sensitive than the combination of CT and visceral angiography. A more recent study by Proye et al.⁶¹ evaluated preoperative EUS and SRS in 41 patients with insulinoma and gastrinoma. The sensitivity and positive predictive value of EUS were 77% and 94%, respectively, for pancreatic tumors; 40% and 100%, respectively, for duodenal gastrinomas; and 58% and 78%, respectively, for metastatic lymph nodes. These results indicate that EUS is best at detecting lesions in the head of the pancreas. It is less successful at evaluating the distal pancreas and the duodenal wall. Additionally, the procedure is operator dependent.⁶² These results have been duplicated by others and have led some to suggest that EUS should serve as the initial localization procedure in patients with insulinoma and gastrinoma. Of note, the drawback to EUS is that it does not evaluate accurately for hepatic metastatic disease; rather, it is more sensitive than CT for

FIGURE 55.3. Endoscopic ultrasonographic image from a patient with an insulinoma (arrows) in the body of the pancreas. SV, splenic vein. (From Rosch T, Lightdale CJ, Botet JF, et al. Localization of pancreatic endocrine tumors by endoscopic ultrasonography. *N Engl J Med* 1992;326:1721, with permission.)

imaging the duodenal wall, pancreatic parenchyma, and peripancreatic lymph nodes.

Intraoperative Ultrasound

Historically, the primary methods of localizing PENs intraoperatively have been visualization and palpation. With the advent of laparoscopic exploration for PENs, intraoperative ultrasound has been substituted for palpation. Results have been promising, with sensitivities reported between 75% and 90%.^{63,64}

Venous Sampling

Percutaneous transhepatic portal venous sampling (PTPVS) and arterial stimulation with venous sampling (ASVS) are two techniques that are used exclusively for the diagnosis and localization of PENs. In a small number of cases, CT, MRI, SRS, and EUS are unsuccessful at localizing a pancreatic endocrine neoplasm. When insulinoma or gastrinoma are suspected, PTPVS may help in localizing the occult neoplasm.⁶⁵⁻⁶⁹ The technique involves placing a catheter percutaneously through the liver into the portal vein and then sequentially sampling for hormone levels in the splenic vein, superior mesenteric vein, and portal vein, thereby regionalizing the location of hormone production (Fig. 55.4). The overall accuracy of this test ranges from 70% to greater than 95% depending on the number of samples obtained, the persistence of autonomous hormone production by the tumor, and the careful handling and assaying of all samples. ASVS involves the selective visceral arterial injection of secretin or calcium with concurrent hepatic venous sampling for either gastrin or insulin.^{70,71} Gastrinoma cells are known to respond to secretin by releasing gastrin,^{72,73} and insulinoma cells are known to respond to calcium by releasing insulin. The provocative secretagogue is serially injected through an arterial catheter into at least three sites—the splenic, gastroduodenal, and inferior pancreaticoduodenal arteries. Samples are drawn from a hepatic vein catheter before

FIGURE 55.4. Schematic depiction of data from percutaneous transhepatic portal venous sampling (PTPVS) in a patient with an insulinoma. Insulin levels are given in microunits per milliliter. These data localize the neoplasm to the head of the pancreas. (Adapted from Norton JA, Sigel B, Baker AR, et al. Localization of an occult insulinoma by intraoperative ultrasonography. *Surgery* 1985;97:381.)

and immediately after each injection. The arterial supply to the occult tumor can then be deduced based on which selective secretagogue injection is followed by a large increase in hepatic vein hormone concentration (Fig. 55.5). This technique, particularly when combined with intraoperative ultrasonography, results in a sensitivity of greater than 90%, essentially obviating the need for blind resection in unlocalized insulinomas.^{63,74}

FIGURE 55.5. Graphic depiction of the results of arterial stimulation with venous sampling (ASVS) in a patient with gastrinoma. The rise in hepatic vein gastrin concentration (gastrin gradient) is plotted on the y-axis, and basal values are plotted on the x-axis: 1, 100% rise; 2, 200% rise; and so forth. A rise in the hepatic vein gastrin concentration observed after the injection of secretin into the superior mesenteric artery (SMA) and gastroduodenal artery (GDA) localizes the neoplasm to the head of the pancreas or duodenum. SPL, splenic artery. (Adapted from Thom AK, Norton JA, Doppman JL, et al. Prospective study of the use of intra-arterial secretin injection and portal venous sampling to localize duodenal gastrinomas. *Surgery* 1992;112:1002.)

Additionally, ASVS can differentiate the 5% of patients with nesidioblastosis from those with insulinoma.⁷⁵

SURGICAL EXPLORATION

At the time of surgical exploration for PEN, a complete evaluation of the pancreas and peripancreatic regions is performed. The body and tail of the pancreas are exposed by dividing the gastrocolic ligament. This portion of the pancreas can be partially elevated out of the retroperitoneum by dividing the inferior retroperitoneal attachments to the gland. After the second portion of the duodenum has been elevated out of the retroperitoneum by means of the Kocher maneuver, the pancreatic head and uncinate process are palpated bimanually. The liver is carefully assessed for evidence of metastatic disease. Potential extrapancreatic sites of tumor are evaluated in all cases, with particular attention paid to the duodenum, splenic hilum, small intestine and its mesentery, peripancreatic lymph nodes, and reproductive tract in women. The goals of surgical therapy for pancreatic endocrine neoplasms include controlling the symptoms of hormone excess, safely resecting maximal tumor mass, and preserving maximal pancreatic parenchyma. Management strategies, including preoperative, intraoperative, and postoperative considerations, vary for the different types of endocrine neoplasms of the pancreas.

INSULINOMA

Insulinoma is the most common functional neoplasm of the endocrine pancreas (Table 55.5). The insulinoma syndrome is associated with the following features, known as Whipple's triad⁷⁶:

1. Symptoms of hypoglycemia during fasting
2. Documentation of hypoglycemia, with a serum glucose level below 50 mg/dL
3. Relief of hypoglycemic symptoms following administration of exogenous glucose

6 Autonomous insulin secretion in insulinomas leads to spontaneous hypoglycemia, with symptoms that can be classified into two groups (see Table 55.5). Neuroglycopenic symptoms include confusion, seizure, obtundation, personality change, and coma. Hypoglycemia-induced symptoms, related to a surge in catecholamine levels, include palpitations, trembling, diaphoresis, and tachycardia. In most cases, patients consume carbohydrate-rich meals and snacks to relieve or prevent these symptoms.

Whipple's triad is not specific for insulinoma. The differential diagnosis of adult hypoglycemia is extensive and includes the following: reactive hypoglycemia, functional hypoglycemia

associated with gastrectomy or gastroenterostomy, nonpancreatic tumors, pleural mesothelioma, sarcoma, adrenal carcinoma, hepatocellular carcinoma, carcinoid, hypopituitarism, chronic adrenal insufficiency, extensive hepatic insufficiency, and surreptitious self-administration of insulin or ingestion of oral hypoglycemic agents.

A common error made in evaluating a patient with suspected insulinoma is to begin with an oral glucose tolerance test. Instead, insulinoma is most reliably diagnosed by means of a monitored fast. During a monitored fast, blood is sampled for glucose and insulin determinations every 4 to 6 hours and when symptoms appear. Hypoglycemic symptoms typically occur when glucose levels are below 50 mg/dL, with concurrent serum insulin levels often exceeding 25 microunits/mL. Additional support for the diagnosis of insulinoma comes from the calculation of the insulin-to-glucose ratio at different times during the monitored fast. Normal persons have insulin-to-glucose ratios below 0.3, whereas patients with insulinoma typically demonstrate insulin-to-glucose ratios above 0.4 after a prolonged fast. Other measurable β -cell products synthesized in excess in patients with insulinoma include C peptide and proinsulin. Elevated levels of both are typically found in the peripheral blood of patients with insulinoma.

The possibility of the surreptitious administration of insulin or oral hypoglycemic agents should be considered in all patients with suspected insulinoma. Levels of C peptide and proinsulin are not elevated in patients who self-administer insulin. Additionally, patients self-administering either bovine or porcine insulin may demonstrate anti-insulin antibodies in circulating blood. The ingestion of oral hypoglycemic agents, such as sulfonylureas, can be assessed by means of standard toxicologic screening.

Insulinomas are evenly distributed throughout the pancreas, with one third found in the head and uncinate process, one third in the body, and one third in the tail of the gland.⁷⁷ Less than 3% are located outside the pancreas, with these lesions located in the peripancreatic area.⁷⁸ Ninety percent are found to be benign solitary adenomas amenable to surgical cure. Ninety percent of insulinomas are sporadic, with approximately 10% being associated with the MEN-1 syndrome. In patients with MEN-1, the possibility of multiple insulinomas must be considered, and recurrence rates are higher. In approximately 10% of patients, insulinoma is metastatic to the peripancreatic lymph nodes or liver, making the diagnosis of malignant insulinoma.

After the diagnosis of insulinoma has been confirmed biochemically, the appropriate localization and staging studies described earlier are performed (typically CT and EUS). Once the lesion has been localized,⁷⁹ patients undergo surgical exploration, where the pancreas is assessed not only by operative palpation but also by intraoperative ultrasonography. This allows for confirmation of preoperative localization and evaluates for the presence or absence of multiple primary tumors. Small, benign tumors that are not close to the main pancreatic duct can be removed by enucleation⁸⁰ (Fig. 55.6), regardless of their location in the gland. Larger tumors in the neck or proximal body may be resected via central pancreatectomy.^{81–83} In the body and tail of the pancreas, insulinomas more than 2 cm in diameter and those close to the pancreatic duct are most commonly removed via distal pancreatectomy. Large lesions in the head or uncinate process of the gland may not be amenable to local resection and may occasionally require pancreaticoduodenectomy for complete excision.^{84,85} Increasingly, experienced surgeons are utilizing a laparoscopic approach to these tumors. Both laparoscopic pancreatectomy and enucleation are now performed on a routine basis with excellent results.^{86–90}

In rare instances, preoperative localization studies and intraoperative ultrasound fail to identify the tumor. Intraoperative biopsy of the pancreatic tail may help make the diagnosis of nesidioblastosis as the cause of hyperinsulinism. Some authors have recommended a “blind” distal pancreatic resection to the

level of the superior mesenteric vein (60% to 70% pancreatectomy), in the hope of excising an unidentified insulinoma in the body and tail. Others have suggested blind pancreaticoduodenectomy, because the thickness of the gland in this region makes it more likely to harbor an occult neoplasm. The favored approach at the current time is to defer any blind resection, close the patient without pancreatectomy, and perform postoperative selective arterial calcium stimulation with hepatic venous insulin sampling to allow for specific tumor localization and directed surgical excision at a second operation.⁹¹

Approximately 10% of insulinomas are malignant, presenting with lymph node or liver metastases. In the presence of hepatic metastases, resection of the primary tumor and accessible metastases should be considered if it can be performed safely.⁹²⁻⁹⁴ Such tumor debulking can be helpful in reducing hypoglycemic symptoms and improving long-term survival. In patients with unresectable disease, medications such as diazoxide and octreotide can be used to reduce insulin secretion from the tumor, minimizing hypoglycemia. One promising new treatment is everolimus, an oral rapamycin analogue that inhibits mammalian target of rapamycin (mTOR). In a pilot study of patients with refractory hypoglycemia due to metastatic insulinoma, everolimus resulted in improved glycemic control.⁹⁵ Dietary manipulations, including judicious spacing of carbohydrate-rich meals and the consumption of nighttime snacks, can also reduce the number of hypoglycemic episodes. Multiple chemotherapeutic regimens have been used including streptozocin, dacarbazine, doxorubicin, and 5-fluorouracil.⁹⁶⁻⁹⁸ Combination chemotherapy has yielded the highest response rates but has not been shown to be curative.

GASTRINOMA (ZOLLINGER-ELLISON SYNDROME)

In 1955, Zollinger and Ellison described two patients with severe peptic ulcer disease and pancreatic endocrine tumors and postulated that an ulcerogenic agent originated from the

pancreatic tumor.⁹⁹⁻¹⁰¹ It has been estimated that approximately 1 in 1,000 patients with primary duodenal ulcer disease and 2 in 100 patients with recurrent ulcer after ulcer surgery harbor gastrinomas.¹⁰² Seventy-five percent of gastrinomas occur sporadically, and 25% are associated with the MEN-1 syndrome. Historically, the majority of gastrinomas were found to be malignant, with metastatic disease present at the time of initial workup. With increased awareness and screening for hypergastrinemia, the diagnosis of gastrinoma is made earlier and a higher percentage of patients present with benign and potentially curable neoplasms.¹⁰³

The clinical symptoms of patients with gastrinoma are a direct result of increased levels of circulating gastrin (Table 55.6). Abdominal pain and peptic ulceration of the upper gastrointestinal (UGI) tract are seen in up to 90% of patients. Diarrhea is seen in 50% of patients, with 10% having diarrhea as their only symptom. Esophageal symptoms or endoscopic abnormalities resulting from gastroesophageal reflux are seen in up to half of patients. The diagnosis of gastrinoma should

be suspected in several clinical settings, including the initial diagnosis of peptic ulcer disease, recurrent ulcer after medical or surgical therapy, postbulbar ulcer, family history of ulcer disease, ulcer with diarrhea, prolonged undiagnosed diarrhea, MEN-1 kindred, nongastrinoma pancreatic endocrine tumors (high association of secondary hormone elevations), and prominent gastric rugal folds on UGI examination. Serum gastrin levels should be obtained in all of these settings.

In most patients with gastrinoma, the fasting serum gastrin level is greater than 200 pg/mL. Gastrin levels greater than 1,000 pg/mL in the setting of hyperacidity and ulcer disease are virtually pathognomonic for gastrinoma. Because hypergastrinemia can occur in other pathophysiologic states (Table 55.7), fasting hypergastrinemia alone is not sufficient for the diagnosis of gastrinoma. Gastric acid analysis (or at least gastric pH testing) is critical in differentiating between ulcerogenic (high levels of acid) and nonulcerogenic (low levels of acid) causes of hypergastrinemia. To obtain an accurate gastric acid analysis, patients must not be taking antisecretory medications including histamine (H_2)-receptor antagonists or proton pump inhibitors (PPIs). The diagnosis of gastrinoma is supported by a basal acid output above 15 mEq/h in nonoperated patients, a basal acid output exceeding 5 mEq/h in patients with previous vagotomy or ulcer operations, or a ratio of basal acid output to maximal acid output exceeding 0.6.

After documenting that hypergastrinemia and excessive acid secretion exist, provocative testing with secretin should be performed to differentiate between gastrinoma, antral G-cell hyperplasia or hyperfunction, and the other causes of ulcerogenic hypergastrinemia. This is achieved with a secretin stimulation test (Fig. 55.7). A baseline gastrin level is drawn. The patient is then stimulated with 2 units per kilogram of secretin as an intravenous bolus and subsequent gastrin samples are collected at 5-minute intervals for 30 minutes. An increase in the gastrin level by more than 200 pg/mL above the basal level supports the diagnosis of gastrinoma.

After the biochemical diagnosis of gastrinoma has been made, the gastric acid hypersecretion should be pharmacologically controlled. The PPIs are now considered the drugs of choice for doing so.^{104,105} The dose is adjusted to achieve a nonacidic pH during the hour immediately before the next dose of the drug. Typically, PPI doses needed for acid control exceed usual dosing levels. After the initiation of antisecretory therapy, all patients should undergo imaging studies to localize the primary tumor and to assess for metastatic disease.

If localization studies reveal unresectable hepatic metastases, the patient should undergo percutaneous or laparoscopic-directed liver biopsy to obtain a definitive histologic diagnosis. These patients should be maintained on long-term PPI therapy. Virtually all patients can be rendered achlorhydric with an

FIGURE 55.7. Results of intravenous secretin stimulation tests in patients with atrophic gastritis (triangles), gastric outlet obstruction (squares), and gastrinoma (circles). A positive test result, consistent with the presence of gastrinoma, is indicated by an increase over basal serum gastrin levels of at least 200 pg/mL. (Adapted from Wolfe MM, Jensen RT. Zollinger-Ellison syndrome: current concepts in diagnosis and management. *N Engl J Med* 1987;317:1200.)

appropriate dose of PPIs. Patients noncompliant with antisecretory therapy who experience complications related to their ulcer diathesis may require removal of the end organ (total gastrectomy) if tumor resection is not possible. However, total gastrectomy, once the operation of choice for gastrinoma, is now only rarely used.

If unresectable disease is not identified by staging studies, patients should be offered surgical exploration with curative intent. On exploration, the entire abdomen should be assessed for areas of extrapancreatic and extraduodenal gastrinoma. **9** Most gastrinomas are found in the *gastrinoma triangle*^{77,106} (Fig. 55.8), the area to the right of the superior mesenteric vessels, in the head of the pancreas or in the duodenal wall. Both intraoperative ultrasound and intraoperative upper endoscopy may be helpful in tumor localization. Transillumination of the duodenum may help identify small duodenal gastrinomas.^{107,108} Well-encapsulated tumors less than 2 cm in size and distant from the pancreatic duct can be enucleated. Those situated deep

FIGURE 55.8. Most gastrinomas are found within the gastrinoma triangle. (Adapted from Stabile BE, Morrow DJ, Passaro E. The gastrinoma triangle: operative implications. *Am J Surg* 1984;147:26.)

in the parenchyma may require partial resection by pancreaticoduodenectomy or distal pancreatectomy. If no pancreatic tumor is identified, a longitudinal duodenotomy should be performed at the level of the second portion of the duodenum in search of duodenal microgastrinomas.^{109,110} Small gastrinomas in the duodenal wall can be locally resected with primary closure of the duodenal defect. The routine use of duodenotomy increases the short- and long-term cure rates in patients with sporadic gastrinoma, because such a duodenotomy allows detection of more duodenal gastrinomas.¹¹¹ Duodenotomy did not impact the occurrence of hepatic metastases or disease-related mortality. In a small percentage of patients, gastrinoma is found only in peripancreatic lymph nodes, with these lymph nodes harboring the apparent primary tumor. Resection of these apparent lymph node primary gastrinomas has been associated with long-term eugastrinemia and biochemical cure in up to half of cases.¹¹² A review from the National Institutes of Health identified likely primary lymph node gastrinomas in 26 of 176 gastrinoma patients (14.7%), with 69% being eugastrinemic at a mean of 10 years after resection.¹¹³

Occasionally, preoperative localization studies may identify the tumor in the gastrinoma triangle, but at the time of exploration, the tumor is not demonstrable. Several surgical options are available at this point. First, a parietal cell vagotomy has been proposed as a way to reduce antisecretory drug dose requirements in patients on high-dose antisecretory drug therapy but without prior life-threatening complications.¹¹⁴ However, this approach leaves behind potentially resectable gastrinoma and has lost favor as an option. A second option is total gastrectomy; however, the availability of PPIs has drastically reduced the need to perform this operation for gastrinoma. It may have a limited role in patients whose tumors cannot be localized, if they cannot or will not take their PPIs. Like parietal cell vagotomy, this leaves tumor behind. A third, controversial option in patients with localization to the gastrinoma triangle is blind pancreaticoduodenectomy. Some argue this should include distal gastrectomy, as duodenal gastrinomas may arise close to the pylorus and be left behind during a pylorus-preserving resection.

Patients with sporadic gastrinomas tend to fare better following resection than those with MEN-1. In a series of 151 patients reported by Norton et al.,¹¹⁵ 123 had sporadic gastrinoma and 28 had MEN-1-associated gastrinoma. Of those with sporadic gastrinoma, 34% were free of disease 10 years following resection. None of the MEN-1 patients were free of disease at 10 years. A more recent review of 195 patients from the same institution demonstrated clear superiority of surgical intervention over other treatment strategies.¹¹⁶ The rate of disease-related death was increased 23-fold in the group of patients treated without surgery. These data provide compelling evidence that patients with sporadic gastrinoma benefit from surgical exploration and complete tumor resection.

The management of gastrinoma in MEN-1 is not as clear. The surgical treatment of hypercalcemia caused by parathyroid hyperplasia should precede any surgery for hypergastrinemia in patients with MEN-1. In these patients, gastrin-secreting tumors are often multicentric and associated with lymph node metastases. Although some groups have favored exploration only when MEN-1 gastrinoma tumors exceed 3 cm, it seems that earlier intervention may be warranted.^{117,118} Unfortunately, more data from an appropriate clinical trial are needed to better define the timing of surgery for MEN-1 gastrinoma.

In the 1950s and 1960s, most gastrinomas were diagnosed late in the course of the disease, when the tumor burden was already significant. At that time, effective medical therapy did not exist, nor did sophisticated radiographic localization and staging techniques. Patients often suffered multiple ulcer complications, required total gastrectomy to control the ulcer diathesis, and typically succumbed to continued tumor growth following gastrectomy. Recent reviews of patients with surgically treated gastrinoma provide room for optimism.^{119–122}

Currently, up to 35% of patients who undergo resection with curative intent have been rendered eugastrinemic at follow-up. Cure rates approach 60% to 70% when the extent of disease allows a complete resection.

Most patients with incurable metastatic disease eventually die of tumor growth and dissemination. Multiple modalities have been used to treat such patients. Chemotherapy including streptozocin, 5-fluorouracil, and doxorubicin provides response rates of less than 50%.¹²³ Hormonal therapy with octreotide may relieve symptoms, reduce hypergastrinemia, and diminish hyperchlorhydria.^{124,125} In patients with hepatic metastases, aggressive resection for debulking,^{126–129} hepatic transplantation,¹³⁰ hepatic artery embolization, and interferon therapy have all been used, with variable results.

VIPOMA (VERNER-MORRISON SYNDROME)

Synonyms for VIPoma include WDHA syndrome (watery diarrhea, hypokalemia, and either achlorhydria or acidosis) and pancreatic cholera syndrome (Table 55.8). Verner and Morrison¹³¹ characterized this secretory diarrheal syndrome in a 1958 report. Patients characteristically present with intermittent, severe, watery diarrhea averaging up to 5 L/d. Hypokalemia results from fecal loss of large amounts of potassium. Low serum potassium levels lead to lethargy, muscle weakness, and nausea. A metabolic acidosis may be present, due to loss of bicarbonate in the diarrhea. Half of the patients may have hyperglycemia or hypercalcemia, and cutaneous flushing can be observed in a minority. The diagnosis of VIPoma is made after other common causes of diarrhea have been excluded (Table 55.9)¹³² and an elevated serum VIP level is documented.

VIP secretion can be episodic, so repeated fasting levels should be measured if there is a strong clinical suspicion. Preoperative tumor localization is critical, because 10% of patients may have extrapancreatic tumors located in the retroperitoneum or chest. Most tumors are located in the distal pancreas where they are amenable to resection via distal pancreatectomy (Fig. 55.9). In most cases, hepatic metastases accompany the primary tumor. Therapies directed at debulking these metastases such as resection or ablative strategies are appropriate.

Surgical excision is appropriate in nearly all patients with Verner-Morrison syndrome. Prior to surgery, fluid and electrolyte imbalances must be corrected. Octreotide can serve as a treatment adjunct, reducing the levels of circulating VIP,

TABLE 55.8 **DIAGNOSIS**

VIPOMA

■ PARAMETER	■ DESCRIPTION
Symptoms	Watery diarrhea Weakness Lethargy Nausea
Diagnostic tests	Hypokalemia Achlorhydria Metabolic acidosis Serum VIP levels elevated
Anatomic localization	Most in body and tail of pancreas, with liver metastases
VIP, vasoactive intestinal peptide.	

TABLE 55.9 **DIAGNOSIS****DIFFERENTIAL DIAGNOSIS OF VERNER-MORRISON SYNDROME**

■ ENTITY	■ WORKUP
Villous adenoma	Lower GI endoscopy
Laxative abuse	Stool examination for phenolphthalein
Celiac disease	Fecal fat measurement D-xylose tolerance test Small bowel biopsy
Parasitic and infectious diseases	Stool culture Ovum and parasite analysis <i>Clostridium difficile</i> toxin assay
Inflammatory bowel disease	Lower GI endoscopy Upper GI and small bowel series
Carcinoid syndrome	Urinary 5'-HIAA Upper GI and small bowel series Abdominal CT Serum serotonin measurement
Gastrinoma	Serum gastrin measurement Gastric acid analysis Secretin stimulation test

CT, computed tomography; GI, gastrointestinal; 5'-HIAA, 5'-hydroxyindoleacetic acid.

TABLE 55.10 **DIAGNOSIS****GLUCAGONOMA**

■ PARAMETER	■ DESCRIPTION
Symptoms	Dermatitis manifested as necrolytic migratory erythema Stomatitis Catabolic state: weight loss
Diagnostic tests	Hyperglycemia Hypoproteinemia Serum glucagon measurement Serum amino acid profile
Anatomic localization	Most in body and tail of pancreas, with liver metastases

with a resultant decrease in the volume of diarrhea. Octreotide is also useful for symptom control in the setting of unresectable disease. Chemotherapy specific for this disease has not been well studied.

GLUCAGONOMA

- 10 The most common findings in the glucagonoma syndrome are severe dermatitis, mild diabetes, stomatitis, anemia, and weight loss (Table 55.10). The dermatitis manifests as a characteristic skin rash termed *necrolytic migratory erythema*. This rash

FIGURE 55.9. Several computed tomographic images from a patient with a primary vasoactive intestinal polypeptide-oma (VIPoma) in the tail of the pancreas. The tumor is nearly spherical. Its location is posterior to the stomach and adjacent to the spleen.

FIGURE 55.10. Computed tomography with oral and intravenous contrast in a patient with a glucagonoma. The large tumor appears to be posterior to the stomach and to the right of the aorta from the viewer's perspective.

exhibits cyclic migrations, and it has been theorized that the hypoglycemia accompanying glucagonoma is the cause.

The diagnosis of glucagonoma is suggested by the clinical presentation and biopsy of the skin lesions but is secured by the documentation of high fasting levels of serum glucagon. Most glucagonomas are located in the body and tail of the gland. These tumors are typically large and bulky, and surgical resection requires distal pancreatectomy (Fig. 55.10). Metastases are found in most patients and safe debulking of these should be considered.¹³³ As in patients with VIPoma and insulinoma, octreotide can be useful in controlling the signs and symptoms (hyperglycemia and dermatitis) associated with incurable glucagonoma.

SOMATOSTATINOMA

The somatostatinoma syndrome is the least common of the five generally accepted functional pancreatic endocrine neoplasia syndromes, occurring in less than 1 in 40 million people. The clinical features are nonspecific including steatorrhea, diabetes, hypochlorhydria, and cholelithiasis (Table 55.11). Fasting plasma somatostatin levels of greater than 100 pg/mL can be used to confirm the diagnosis.

Most somatostatinomas are located in the pancreatic head or peripancreatic region.¹³⁴ Tumors are of variable size and are often easily localized. Metastatic disease may be present at the time of diagnosis. Safe resection of the primary tumor (often

via pancreaticoduodenectomy) and careful debulking of hepatic metastases are indicated.

NONFUNCTIONAL ISLET CELL TUMORS

Currently, the majority of patients with neoplasms of the endocrine pancreas have no defined clinical syndrome and no elevated hormone levels. One hormone that may be elevated in these patients is pancreatic polypeptide, but this is not associated with a clinical syndrome. Another elevated serum marker may be chromogranin A. A study by Mutch et al.¹³⁵ determined a relationship between fasting plasma PP levels in patients with MEN-1 and the presence of radiographically detectable pancreatic endocrine tumor. A PP level that is more than three times the age-specific normal value is 95% sensitive and 88% specific for an islet cell tumor that can be imaged. Patients with nonfunctional endocrine tumors typically present with abdominal pain, weight loss, and jaundice, caused by the space-occupying nature of the mass in the pancreas. Overall, nonfunctional tumors tend to grow more slowly and have a much more indolent course and a better survival rate than pancreatic ductal adenocarcinoma. Even patients with locally advanced disease have a median survival in excess of 5 years.^{136,137} Patients with resectable disease should undergo resection for potential cure via pancreaticoduodenectomy or distal pancreatectomy, depending on tumor location.

METASTATIC PANCREATIC ENDOCRINE TUMORS

At least one third of patients with malignant PENs present with synchronous liver metastases at the time of diagnosis.¹³⁸ A subset of these patients remain asymptomatic and experience prolonged survival even without aggressive therapy.⁹⁶ However, overall 5-year survival with liver metastases is less than 50%.¹³⁹ PENs are one of the few tumors for which a survival advantage for surgical debulking has been shown.^{127,138,140-142} In those selected patients where safe surgical resection of greater than 90% of the tumor burden can be achieved, 5-year survival rates of 60% to 75% have been reported.

Those with unresectable disease have shown partial responses to chemotherapy. In 1992, the results of a trial conducted by the Eastern Cooperative Oncology Group (ECOG) were published.⁹⁶ In this study, 105 patients with advanced nonfunctional endocrine tumors were randomly assigned to one of three groups. The lowest response rate (30%) was seen in patients receiving chlorozotocin alone, an intermediate response rate (45%) was seen in patients receiving the combination of streptozotocin plus 5-fluorouracil, and the highest response rate (69%) was noted in patients receiving streptozotocin plus doxorubicin. The last regimen also showed significant survival advantage in comparison with the other two treatments. More recent attempts to replicate these results have been disappointing.¹⁴³

Somatostatin analogues are another approach to treating metastatic PENs. Results are more favorable in tumors that have high-affinity receptors (gastrinomas, VIPomas, glucagonomas, and some nonfunctional tumors) as compared to insulinomas. Symptomatic improvement occurs in 60% to 90% of patients. However, an objective tumor response is seen in only 5% to 15% of patients, with stabilization of disease in 50% or more of patients.¹⁴⁴⁻¹⁴⁶

Multiple investigational agents have been tried in the setting of advanced metastatic PEN. One promising agent is sunitinib malate (Sutent, Pfizer Inc.), an oral multikinase inhibitor approved for the treatment of advanced renal cell carcinoma and refractory gastrointestinal stromal tumors. Interim analysis

TABLE 55.11 **DIAGNOSIS**

SOMATOSTATINOMA

■ PARAMETER	■ DESCRIPTION
Symptoms	Steatorrhea Right upper quadrant pain
Diagnostic tests	Hyperglycemia Hypochlorhydria Gallstones Serum somatostatin level
Anatomic localization	Most in head or uncinate process of pancreas; often peripancreatic

of a phase III trial showed significant benefit in the group taking sunitinib and the trial was halted early.¹⁴⁷

CHAPTER 56 ■ HEPATOBIILIARY ANATOMY

RICHARD D. SCHULICK

KEY POINTS

- 1 The most widely accepted nomenclature for liver anatomy is based on Couinaud's description of eight anatomic segments of the liver.
- 2 There are three major hepatic veins, with most patients having a right hepatic vein that joins the right anterior wall of the inferior vena cava (IVC) and a middle and left hepatic vein that converge into a common trunk before joining the IVC.
- 3 Classic hepatic arterial anatomy exists in only approximately 50% of patients, with a replaced or accessory right hepatic artery arising from the superior mesenteric artery and a replaced or accessory left hepatic artery arising from the left gastric artery being the most common variants.
- 4 Callot's triangle is bounded by the common hepatic duct on the left, the cystic duct inferiorly, and the cystic artery superiorly.
- 5 The blood supply of the common bile duct is segmental in nature and consists of branches from the cystic, hepatic, and gastroduodenal arteries, which meet to form collateral vessels that run in the 3 o'clock and 9 o'clock positions.
- 6 Multiphase computerized tomography magnetic resonance imaging with intravenous contrast are commonly used to characterize hepatic lesions.
- 7 Magnetic resonance cholangiopancreatography is often used to view biliary anatomy as it involves no contrast agent and optimally can provide images that rival formal cholangiography.
- 8 Intraoperative ultrasonography is used routinely to assess the anatomy of the hepatic pedicles (portal vein, hepatic artery, bile duct) and hepatic veins and to identify and characterize hepatic lesions within the parenchyma and their relationships within the eight anatomic segments.
- 9 The portal pedicles are invested with the Glisson capsule and have a very echogenic covering to them on ultrasound in contrast to hepatic vein branches.
- 10 The steps involved in major hepatectomy include optimal exposure, vascular inflow control, vascular outflow control, and parenchymal transection.

A precise knowledge of the anatomy of the liver and biliary tract and their relationship to associated blood vessels is essential for the performance of hepatobiliary surgery. Every surgeon caring for a patient with a hepatobiliary problem should have a thorough understanding of the general anatomy and an absolute understanding of each individual patient's anatomy, because variations are common.

TOPOGRAPHIC ANATOMY

The normal adult liver is a large, wedge-shaped organ that occupies much of the right upper quadrant of the abdomen. Most of the liver bulk lays to the right of the midline where it molds to the undersurface of the right diaphragm, and where the lower border coincides with the right costal margin. The liver extends as a wedge to the left of the midline between the anterior surface of the stomach and the left dome of the diaphragm. The anterior surface of the liver is invested by visceral peritoneum that extends to the anterior abdominal wall in the midline from the ligamentum teres, or round ligament (the obliterated umbilical vessels), and by an obliquely oriented fusion of peritoneum known as the falciform ligament. Posteriorly, the investing peritoneum is contiguous with the peritoneum of the diaphragm and covers the liver, except for a *bare area* bounded by the *right and left triangular ligaments* (Fig. 56.1). The Glisson capsule is a thin, fibrous covering that envelops the liver deep to the peritoneum, sending fibrous septa into the hepatic parenchyma investing the portal structures.

Ordinarily, the liver can be separated from adjacent organs and structures by simply moving it or dividing loose areolar tissue (Fig. 56.2). Neoplastic or inflammatory conditions may obliterate these planes. Superiorly and anteriorly, the diaphragm

or abdominal wall and liver may jointly be involved in a pathologic process. Posteriorly, the right adrenal gland or upper pole of the right kidney may involve or be involved by the liver. Inferiorly, the gallbladder, colon, duodenum, or periportal lymphatics may be involved. Cancers of the stomach or gastroesophageal junction may involve the left liver or vice versa.

MORPHOLOGIC AND FUNCTIONAL ANATOMY

The description and definition of the anatomic divisions of the liver have been revised and written about numerous times in the past 100 years.¹⁻⁸ At present, there is still confusion between the various hepatic anatomic nomenclatures in the English and French literature. Based only on morphologic criteria and surface anatomy, the liver can be divided into right and left halves by forming a plane through the gallbladder fossa (Cantlie line) and inferior vena cava (IVC) (Fig. 56.3). As will be shown later, this plane approximates the true division between the right and left halves using the more strict definition of a plane through the middle hepatic vein and IVC, but the middle hepatic vein is not obvious based solely on morphology and without ultrasound. Further subdivisions of the right half of the liver into a right anterior sector and a right posterior sector are not possible based only on surface anatomy. The left half of the liver can be further subdivided into a left medial section and left lateral section based on the umbilical fissure and falciform ligament. The caudate (tail-shaped) process of the liver is identified as lying posterior to the gastrohepatic ligament and emanating from a process of liver situated posterior to the main portal pedicle and anterior to the IVC.

FIGURE 56.1. Posterior view of the liver, showing the level of peritoneal reflections.

FIGURE 56.2. Posterior view of the liver, showing organs that produce impressions on its inferior surface.

FIGURE 56.3. Anatomic division of the liver into right and left halves by a plane extending from the gallbladder fossa posteriorly to the inferior vena cava.

FIGURE 56.4. Functional divisions of the liver and liver segments according to Couinaud's nomenclature.

1 The most widely accepted nomenclature is based on Couinaud's description of the discrete anatomic segments of the liver (Fig. 56.4).⁶ The eight segments of a liver can be determined using surface anatomy and location of the three main hepatic veins, the portal pedicle bifurcation into right and left, and the umbilical fissure and falciform ligament. As described, the right and left halves of the liver are delineated by a plane through the middle hepatic vein and IVC. Segments II, III, and IV lie to the left of this plane and form the left half of the liver. Segments V, VI, VII, and VIII lie to the right of this plane and form the right half of the liver. Segment I, or the caudate process, is morphologically distinct from the two halves of the liver and emanates from a process of liver lying posterior to the portal pedicle and anterior to the IVC. Whereas the right and left halves of the liver derive blood supply from the corresponding right and left portal veins and hepatic arteries, segment I derives blood supply from both. Additionally, the right half of the liver has venous drainage primarily through the right and middle hepatic veins, and the left half of the liver primarily through the left and middle hepatic veins. Segment I, however, drains directly via small branches into the IVC. The left liver and especially the right liver usually have small accessory hepatic venous branches draining directly into the inferior vena cava. Occasionally on the right, the accessory branch is significant in size.

The right half of the liver can be further subdivided using a plane through the right hepatic vein and the IVC. Liver anterior to this plane forms the right anterior sector, and liver posterior to this plane forms the right posterior sector. The right anterior sector of the liver is composed of segment V (inferior to the portal bifurcation) and segment VIII (superior to the portal bifurcation). The right posterior sector of the liver is composed of segment VI (inferior to the portal bifurcation) and segment VII (superior to the portal bifurcation).

The left half of the liver can be further subdivided using a plane through the umbilical fissure and falciform ligament. Liver medial to this plane forms the left medial section of the liver or segment IV, and liver lateral to this plane forms the left lateral section of the liver. The left medial section of the liver is sometimes divided into two halves, with IVa closer to the inferior vena cava and IVb farther. The left lateral section of the liver is further subdivided into segment II (which is superior) and segment III (which is inferior).

Hepatic Veins

2 Three major hepatic veins carry blood from the liver to the IVC. Most patients have a right hepatic vein that joins the

right anterior wall of the IVC and a middle and left hepatic vein that converge into a common trunk about 1 cm from the IVC that enters the left anterior wall of the IVC (Fig. 56.5). In some patients, the three main hepatic veins join the IVC via three distinct trunks. These hepatic veins usually lie within the hepatic parenchyma. Usually, a definable extraparenchymal segment of the hepatic veins, especially the right, can be dissected out before it empties into the IVC, which makes outflow control safer and easier. Usually, multiple accessory right hepatic veins empty from the right half of the liver directly into the IVC as it courses posterior to the liver (Fig. 56.6). On occasion, these accessory right hepatic veins are sizable and may even support venous outflow should the native right hepatic vein need to be taken. Additionally, sometimes an umbilical vein can be appreciated running to the falciform ligament between the middle and left hepatic veins and emptying into the terminal portion of the left hepatic vein.

Portal Veins

The superior mesenteric and splenic veins join posterior to the neck of the pancreas to form the main portal vein. It receives pyloric and coronary vein branches as it courses cephalad and obliquely to the right to form the most posterior structure within the hepatoduodenal ligament (portal triad). In the hilus of the liver, the main portal vein bifurcates into a short oblique right portal vein and a longer, more transverse, and more superficial left portal vein (Fig. 56.7). These branches then enter the parenchyma and become invested along with the other components of the portal triad by extensions of the Glisson capsule. Both the right and left portal veins give off small branches to dually supply segment I. The right portal vein usually enters the hepatic parenchyma immediately and is quick to divide into a right anterior portal vein supplying segments V and VIII and a right posterior portal vein supplying segments VI and VII. The left portal vein may remain near the surface of the left half of the liver in the hilar plate for a significant distance as it courses to the umbilical fissure to give off medial branches to segment IV and lateral branches to segments II and III.

Hepatic Arteries

There is much variability in the hepatic arterial supply to the liver. The most common anatomy is a common hepatic artery that arises from the celiac trunk and courses near the superior border of the neck of the pancreas. After the origins of the

FIGURE 56.5. Three major hepatic veins drain the liver. The caudate segment of the liver usually drains directly into the inferior vena cava.

FIGURE 56.6. Retraction of right liver medially exposes small venous tributaries that drain the right liver directly into the retrohepatic vena cava. Several branches are ligated.

FIGURE 56.7. Intrahepatic divisions of the portal vein.

FIGURE 56.8. Variations in hepatic arterial anatomy.

gastroduodenal, supraduodenal, and right gastric arteries, the proper hepatic artery courses in the left anterior aspect of the hepatoduodenal ligament in front of the portal vein and to the left of the common hepatic duct. The proper hepatic artery usually bifurcates into right and left hepatic arteries outside the liver. The anatomy of the hepatic artery is variable and should be familiar to surgeons operating in this area (Fig. 56.8). Approximately 45% of people have variant hepatic arterial anatomy.⁹ The right hepatic artery usually courses posterior to the common hepatic duct but anterior to the right portal vein to supply the right liver. The left hepatic artery usually remains extrahepatic until near the base of the umbilical fissure, where it enters the liver to give off branches to segments II, III, and IV. Small branches from near the bifurcation of the proper hepatic artery also supply segment I. A middle hepatic artery branch may arise from either the right or left hepatic arteries after bifurcation. Although this anatomy is described as normal, it is found only in approximately 50% to 60% of patients. A replaced or accessory right hepatic artery may arise off of the superior mesenteric artery near its origin and course

posteriorly or through the head of the pancreas to lie along the right posterior border of the hepatoduodenal ligament. A replaced or accessory left hepatic artery may arise off of the left gastric artery and course transversely toward the base of the umbilical fissure in the lesser omentum. In general, within the hepatic parenchyma, the hepatic arterial branches course closely with bile duct branches and fairly closely with portal venous branches, but not always, and anatomic variations should be suspected. The descriptions and frequency of hepatic arterial variants have been well characterized by Michels.⁹

Intrahepatic Biliary Tree

The right and left livers are respectively drained by the right and left hepatic ducts, whereas the caudate (segment I) is drained by several small ducts joining the bifurcation and the first several centimeters of both hepatic ducts. The intrahepatic ducts are tributaries of the corresponding hepatic ducts, which penetrate the liver invaginating the Glisson capsule at the

FIGURE 56.9. Intrahepatic divisions of the bile ducts and hepatic arteries.

hilus. Bile ducts are usually located above the corresponding portal branches, whereas hepatic arterial branches run inferiorly to the veins. The left hepatic duct directly drains the bile ducts to segments II, III, and IV, which constitute the left liver. The right hepatic duct drains the bile ducts from segments V,

VI, VII, and VIII, which constitute the right liver. Usually, the bile ducts from segments V and VIII join to first form the anterior sectoral duct and the bile ducts from segments VI and VII join to first form the posterior sectoral duct prior to forming the right hepatic duct (Fig. 56.9).

Gallbladder

The gallbladder is a reservoir for bile located on the undersurface of the liver at the confluence of the right and left halves of the liver. It is separated from the hepatic parenchyma by a cystic plate, which is constituted of connective tissue applied to the Glisson capsule. The gallbladder may be deeply imbedded into the liver or occasionally presents on a mesenteric attachment, but usually lays in a gallbladder fossa. The gallbladder varies in size and consists of a fundus, a body, and an infundibulum. The tip of the fundus usually reaches the free edge of the liver and is closely applied to the cystic plate. The infundibulum of the gallbladder makes an angle with the body and may obscure the common hepatic duct, constituting a danger point during cholecystectomy. The cystic duct arises from the infundibulum of the gallbladder and extends to join the common hepatic duct. The lumen measures between 1 and 3 mm in diameter, and its length varies depending on the type of union with the common hepatic duct (Fig. 56.10). Callot's triangle is bounded by the common hepatic duct on the left, the cystic duct inferiorly, and the cystic artery superiorly. Arterial blood reaches the

FIGURE 56.10. Variations in the junction of the cystic duct and common hepatic duct.

FIGURE 56.11. Variations of the cystic artery.

gallbladder via the cystic artery, which usually originates from the right hepatic artery. Several known variations in the origin and course of the cystic artery are illustrated in Figure 56.11. The venous drainage of the gallbladder is directly into the liver parenchyma or into the common bile duct plexus.

Common Bile Duct

The cystic and common hepatic ducts join to form the common bile duct. The common bile duct is approximately 8 to 10 cm in length and 0.4 to 0.8 cm in diameter. The common bile duct can be divided into three anatomic segments: supraduodenal, retroduodenal, and intrapancreatic (Fig. 56.12). The supraduodenal segment resides in the hepatoduodenal ligament lateral to the hepatic artery and anterior to the portal vein (Fig. 56.13). The course of the retroduodenal segment is posterior to the first portion of the duodenum, anterior to the inferior vena cava, and lateral to the portal vein. The pancreatic portion of the duct lies within a tunnel or groove on the posterior aspect of the pancreas. The common bile duct then enters the medial wall of the duodenum, courses tangentially through the submucosal layer for 1 to 2 cm, and terminates in the major papilla in the second portion of the duodenum (Fig. 56.12). The distal portion of the duct is encircled by smooth muscle that forms the sphincter of Oddi. The common bile duct usually joins the pancreatic duct to form a common channel before entering the duodenum at the ampulla of Vater. Some patients will have an accessory pancreatic duct emptying into the duodenum.

- 5 The blood supply of the common bile duct is segmental in nature and consists of branches from the cystic, hepatic, and gastroduodenal arteries. These meet to form collateral vessels that run in the 3 and 9 o'clock positions. The venous drainage forms a plexus on the anterior surface of the common bile

duct that enters the portal system. The lymphatic drainage follows the course of the hepatic artery to the celiac nodes.

LIVER IMAGING

Computed Tomography

Computed tomography (CT) is widely available and quick and has become the main modality to initiate the assessment of hepatic processes. It also has the advantage of being able to quickly assess other organs within the abdominal cavity and chest. With the introduction of multidetector spiral CT, the resolution of hepatic lesions is quite good. This scanning technique allows total hepatic imaging in arterial, portal venous, and delayed phases after a rapid intravenous contrast bolus during a single breath hold by the patient (Fig. 56.14). In addition, three-dimensional reconstructions can be obtained to construct hepatic arteriograms that approach the quality of invasive angiography.

Magnetic Resonance Imaging

- 6 Magnetic resonance imaging (MRI) of the liver with gadolinium as a contrast agent is commonly used to help further characterize hepatic lesions. Resolution of some lesions may be slightly better with MRI. Additionally, certain lesions, such as hemangiomas and cysts, can easily be identified based on MRI characteristics when the CT characteristics are indeterminate (Fig. 56.15). The disadvantages of MRI are its increased cost, increased amount of time to perform, inability to quickly screen other organs and body cavities within the same session, and wide variability in quality from one imaging center to another.

FIGURE 56.12. Anatomy of the extra-hepatic biliary tree and pancreatic duct.

7 Magnetic resonance cholangiopancreatography (MRCP) is becoming more widely used to noninvasively view biliary anatomy (Fig. 56.16). The scans are heavily T2 weighted, which maximizes the signal from the biliary tree. No injection of contrast agent is needed, and under optimal conditions the resulting imaging can rival that of formal cholangiography. Three-dimensional reconstructions can be performed to view the biliary tree from multiple angles and can be helpful in distinguishing between stones, strictures, and neoplasms.

Ultrasonography

Hepatic ultrasonography can be applied transcutaneously or intraoperatively via open surgery and laparoscopic surgery. It can be useful in identifying lesions within the hepatic parenchyma, to describe the consistency (i.e., fatty or cirrhotic) and identify dilatation of the biliary tree and any abnormalities or stones within the gallbladder. In hepatobiliary surgical centers, intraoperative ultrasonography is used

8

FIGURE 56.13. Relationship of structures within the hepatoduodenal ligament.

FIGURE 56.14. Portal venous phase of computed tomography (CT) scan from a patient with a history of colorectal cancer and three lesions in the liver. Lesion 1 in segment VIII is irregular and rim enhancing and was a colorectal cancer metastasis. Lesion 2 straddling segments IV and VIII has smooth borders, is not rim enhancing, and was found to be a cyst. Lesion 3 straddling segments IV and III across the umbilical fissure is irregular and rim enhancing and was a colorectal cancer metastasis.

routinely to assess the anatomy of the pedicles (portal vein, hepatic artery, bile duct), the hepatic veins, and the hepatic parenchyma. It is useful both to further identify and characterize lesions within the hepatic parenchyma and to delineate their relationships within the eight anatomic segments of the liver. Additionally, it is often helpful to delineate proximity of lesions to major vascular structures and to survey for abnormal anatomy in planning a resection.

With ablational therapies more commonly employed, ultrasound has become indispensable in directing the use of radiofrequency ablation. This ablational therapy can be performed percutaneously, laparoscopically, and during open surgery.

Typically, intraoperative assessment of the liver involves examining the portal pedicles. The main portal pedicle is identified within the hepatoduodenal ligament. It is followed superiorly to the portal bifurcation into the main right and

9 left pedicle. The portal pedicles are invested with the Glisson capsule and have a very echogenic covering to them in contrast to hepatic vein branches. The main right portal pedicle is followed toward the right where it gives off an anterior and posterior branch (Fig. 56.17A). The right anterior branch gives off separate pedicles to segment V (caudad) and to segment VIII (cephalad). The right posterior branch gives off separate pedicles to segment VI (caudad) and to segment VII (cephalad). The main left pedicle is usually much longer and courses intact to the base of the umbilical fissure before branching into various segmental pedicles (Fig. 56.17B). At the base of the umbilical fissure, the main left pedicle courses anteriorly toward the round ligament and gives off a pedicle to segment IV medially and pedicles to segments II and III laterally. Next, if the falciform ligament has been divided, the hepatic veins can easily be visualized using intraoperative ultrasonography (Fig. 56.17C). As described previously, usually a larger right hepatic vein can be delineated and smaller left and middle hepatic veins joining into a common trunk before emptying into the IVC are seen. Commonly, an umbilical hepatic vein branch can be identified coursing between the middle and left hepatic veins and running under the falciform ligament. Not uncommonly, significant accessory right hepatic veins can be seen emptying from the posterior surface of the right liver directly into the IVC as it courses posterior to the liver. The identification of these accessory right hepatic veins is potentially important for both vascular control and preservation of outflow from the liver (in occasional cases where outflow of the remnant right liver can be supported by a very large accessory vein). Lastly, the hepatic parenchyma is systematically scanned to identify lesions within the liver (Fig. 56.17D). It is sometimes useful to adjust the ultrasound settings on a known lesion defined preoperatively to maximize the echogenicity in the hopes of identifying other occult lesions not identified preoperatively.

Positron Emission Tomography

Positron emission tomography (PET), especially when combined with CT (PET-CT), has become a valuable tool in helping to select patients who will most benefit from aggressive liver resection. This technique is based on the increased metabolism of glucose in neoplastic tissues. A glucose analogue, fluorodeoxyglucose, that is tagged with fluorine 18 is injected intravenously before scanning and is retained preferentially in metabolically active tumors over normal tissue. Sometimes PET scans will identify areas of occult disease within the liver, but more importantly, they can identify areas of extrahepatic occult disease previously unsuspected. When combined with a CT scanner within the same machine and the ability to fuse images, the areas of increased activity can be more precisely anatomically identified (Fig. 56.18).

Correlation of Computed Tomographic Images with Segmental Anatomy

Preoperative CT remains the primary imaging modality used by most surgeons before hepatic resection. Figure 56.14 is provided to help correlate CT images to the segmental anatomy defined previously. The segments of the liver are defined using identifiable structures on the CT (Fig. 56.19).

PREOPERATIVE EVALUATION OF HEPATIC RESERVE

Whenever a surgical resection is planned, an important consideration is whether the remnant liver will be sufficient to regenerate and sustain the patient long term. In patients with

FIGURE 56.15. A, B: T1-weighted magnetic resonance imaging (MRI) with gadolinium from the same patient as in Figure 58.14 with history of colorectal cancer and three lesions in the liver. Lesion 1 in segment VIII is irregular and rim enhancing and was a colorectal cancer metastasis. Lesion 2 straddling segments IV and VIII has smooth borders, is not rim enhancing, and was found to be a cyst. Lesion 3 straddling segments IV and III across the umbilical fissure is irregular, rim enhancing, and was a colorectal cancer metastasis. C, D: T2-weighted MRI from same patient with history of colorectal cancer and three lesions in liver. Lesion 1 in segment VIII is irregular and mildly bright and was a colorectal cancer metastasis. Lesion 2 straddling segments IV and VIII has smooth borders, is very bright, and was found to be a cyst. Lesion 3 straddling segments IV and III across the umbilical fissure is mildly bright and was a colorectal cancer metastasis. Colorectal metastases and many tumors are mildly bright on T2-weighted MRI, whereas cysts and hemangiomas are typically very bright.

relatively normal hepatic parenchyma (without active hepatitis, cirrhosis, or metabolic defects), up to 75% of the hepatic volume can be resected with good recovery as long as the remnant liver has adequate portal venous and hepatic arterial inflow, adequate hepatic venous outflow, and adequate biliary drainage. Many groups around the world have used various strategies to predict hepatic reserve (Tables 56.1 and 56.2). None of these tests or strategies has been demonstrated to clearly better predict outcome than another. Many centers in the United States rely simply on the Child-Pugh score and the prediction of adequate liver remnant volume after resection. In select circumstances, it may be of benefit to perform portal vein embolization to the right or left half (rare) of the liver in the hopes of obtaining compensatory hypertrophy of the other side before resection. This is especially useful when the predicted liver remnant after resection is small or if the patient has an underlying hepatic dysfunction that may not allow the remnant to fully regenerate and sustain the patient long term. To gain maximal growth of the left lateral section of the liver, some centers will also embolize the portal vein branches to segment IV in addition the main right portal vein. The disadvantages of portal vein embolization include the need to wait

3 to 4 weeks before resection to allow the compensatory hypertrophy to occur and, for more central lesions, the need to commit to taking out one or the other side with an extended hepatectomy without the benefit of intraoperative evaluation.

TABLE 56.1

STRATEGIES TO PREDICT HEPATIC RESERVE

- Child-Pugh score (Table 56.2) to assess synthetic ability (albumin, prothrombin time, and ascites), bile conjugation and excretory function (total bilirubin), and metabolic function (changes in mental status from ammonia retention)
- Clearance of galactose or organic anionic dyes, such as indocyanine green
- Tests of microsomal function such as caffeine clearance, lidocaine clearance, or aminopyrine breath tests
- Volumetric measurements of the liver and prediction of liver remnant after resection based on three-dimensional reconstructions from computed tomography and magnetic resonance imaging

FIGURE 56.16. Magnetic resonance cholangiopancreatography (MRCP) of a patient after cholecystectomy with mild dilation of common hepatic duct (CHD). The pancreatic duct (PD) is also visible.

TABLE 56.2

CHILD-PUGH CLASSIFICATION

	1 POINT	2 POINTS	3 POINTS
Bilirubin (mg/dL)	<2	2–3	>3

ONCOLOGIC CONSIDERATIONS IN HEPATIC RESECTION

The decision of when and whether to operate is often just as important as the technical details of successfully removing a liver lesion(s) identified in a patient. It is very important to consider the likely diagnosis in making the decision of whether to operate. For example, a solitary liver lesion presenting in an elderly patient with a rising carcinoembryonic antigen (CEA) and a recent history of a resected colon cancer should be treated differently from a young woman with a solitary lesion with radiologic characteristics of a focal nodular hyperplasia lesion. It is important to consider the biology of the tumor within the patient. For example, a patient who re-presents with a solitary hepatic colorectal cancer metastasis 4 years after resection of the primary tumor will more likely benefit from hepatic resection than another patient who presents with eight synchronous lesions in the liver at the time of diagnosis of the primary tumor. It is important to consider whether the goal of resection is curative or palliative. For example, patients with neuroendocrine tumor metastases of the liver may be debulked of hepatic metastases, but they are rarely totally eradicated of disease. If the tumor is functional and difficult to control medically, then there may be a benefit to debulking. Even if the tumor is not functional, some evidence indicates that surgical debulking of liver metastases in carefully selected patients may benefit long-term survival. It is important to exclude other distant extrahepatic disease with a reasonable number of preoperative tests. For example, before performing hepatic resection for colorectal cancer metastases, it is often helpful to obtain a PET scan to exclude extrahepatic metastases. This will allow better selection of patients most likely to benefit from hepatic resection and will allow patients with previously unsuspected systemic disease to get systemic therapy sooner.

The comorbid status of the patient is also important. Extended hepatic resections with or without biliary reconstruction can exert a toll on even very fit patients. It is important to identify patients who may have difficulties with hepatic regeneration (e.g., those with a history of hepatitis, cirrhosis, or metabolic disorders). Patients with suspected cardiopulmonary disease should undergo appropriate preoperative evaluation and treatment before hepatic resection. Lastly, other effective treatments and the optimal sequence of treatments should be considered. For example, in the treatment of hepatocellular carcinoma the possibilities include liver transplantation, liver resection, liver ablation (radiofrequency, cryotherapy, or ethanol), embolization, and systemic chemotherapies. A patient with very poor hepatic reserve because of chronic liver disease and a single small hepatocellular carcinoma may be best treated with liver transplantation, whereas a patient with normal liver parenchyma and a resectable lesion may be best treated with liver resection. Additionally, some patients may best be treated with ablative techniques, especially if they have very small lesions that are easily approached percutaneously. Some patients are treated with a combination of these modalities. For example, some centers will first treat patients with chemoembolization before liver transplantation or resection for hepatocellular carcinoma depending on the waiting time for a liver graft or to test the biology of the disease.

INTRAOPERATIVE ASSESSMENT

Incisions for hepatic resections usually involve a right subcostal incision. Significant exposure can be obtained with a trifurcated incision as shown in Figure 56.20. In the majority of cases, however, all that is needed is an extended right subcostal incision with a vertical extension to the base of the xiphoid. The xiphoid can be resected for better exposure. For bulky lesions on the left or if the left half of the liver extends signifi-

FIGURE 56.20. Incisions used for hepatic resection.

cantly to the left upper quadrant, a left subcostal component can be added. In rare circumstances, especially for lesions high on the dome, an intercostal extension or even median sternotomy may improve exposure. This is especially true for lesions involving the hepatic vein and IVC confluences.

Several versions of self-retaining costal margin retractors or ringed retractors are available that provide good access to the subdiaphragmatic surface. For complete intraoperative ultrasonography and for major resections, complete mobilization of the involved side of the liver is required. The round ligament is divided and the falciform ligament divided. The right and/or left triangular ligaments are then divided to expose the bare areas of the liver. During exposure of the bare areas of the liver, care should be taken to avoid entering the right or left chest through the ligamentous portions of the diaphragm because this will cause excessive bowing of the diaphragm and poor exposure until a chest tube is placed on that side or the hemithorax is “bubbled out” to remove the air and the diaphragm repaired. Additionally, the right and left phrenic veins are very superficial on the hemidiaphragms and can be injured. The right colon can be mobilized out of the field by dividing Gerota fascia over the right kidney and pulling the hepatic flexure inferiorly. To completely assess the caudate lobe, the overlying lesser omentum should be divided. Care should be taken to avoid inadvertently dividing a replaced or accessory left hepatic artery running in this space. After mobilization, a thorough bimanual examination should be performed and intraoperative ultrasonography used as previously described.

The porta hepatis is often dissected to identify the main bifurcations of the hepatic artery, bile duct, and portal vein. This allows individual ligation of the branches of these structures supplying one side of the liver while preserving the branches to the other side. Ligation of the hepatic artery and portal vein to one side also allows the liver parenchyma to demarcate a line of resection between the right and left liver. Greater exposure of the superior aspect of the hepatic hilum and exposure of a high or intraparenchymal bifurcation of a

FIGURE 56.21. Lowering the hilar plate. **A:** The inferior border of segment IV overlies the hepatic duct confluence. **B:** Division of the connective tissue investment allows elevation of segment IV, which results in a “lower” hilar plate and surgical exposure to the hepatic duct confluence. (From Blumgart LH, ed. *Surgery of the Liver and Biliary Tract*. New York: Churchill Livingstone; 1994, with permission.)

portal triad structure may be aided by exposing the hilar plate (Fig. 56.21) and dividing the Glisson capsule at the most inferior border of segment IV. Inflow control to the liver can also be obtained by pedicle ligations in which small hepato-tomies are made around the main right pedicle, main left pedicle, right anterior pedicle, or right posterior pedicle after identification with ultrasound (Fig. 56.22).¹⁰ The pedicle of interest can be dissected out bluntly with a right angle or by palpation. The pedicle can then be clamped to confirm that it does indeed supply the area of liver of interest (i.e., right half, left half, right anterior section, or right posterior section). Once confirmed, the pedicle can be divided. Alternatively, the inflow pedicles can be divided as they are encountered while transecting hepatic parenchyma. With this technique, hemorrhage can be minimized by intermittent portal inflow occlusion, which is accomplished by gently clamping the main portal triad within the hepatoduodenal ligament (“Pringle maneuver”).

Outflow control of the hepatic veins can be obtained before or after hepatic transection and should be decided on a case-by-case basis. When there is a significant extraparenchymal component to the hepatic vein(s), often it is easier to divide the hepatic vein(s) early and before parenchymal transection (but after inflow control) (Fig. 56.23). When the extraparenchymal component to the hepatic vein(s) is very short or absent and when the tumor margin is not near the junction of the hepatic

vein(s) and IVC, it may be easier and safer to divide the hepatic vein(s) within the hepatic parenchyma after most of the parenchymal transection has been performed. The use of endoscopic vascular stapling devices has made the ligation of hepatic veins, whether extra- or intraparenchymally, much quicker and safer¹⁰ (Fig. 56.24). It is often useful to keep the central venous pressure (CVP) of the patient low (<5 mm Hg) until after parenchymal transection as this will decrease bleeding from the IVC and hepatic vein branches.¹¹

MAJOR HEPATECTOMIES

To develop a uniform nomenclature understood by all, the American and International Hepato-Pancreato-Biliary Associations (AHPBA and IHPBA) have adopted the Brisbane 2000 terminology of hepatic anatomy and resections. Right hepatectomy or right hemihepatectomy involves the resection of segments V through VIII. Left hepatectomy or hemihepatectomy involves the resection of segments II through IV. Either of these resections may or may not include resection of segment I, which should be stated. Extended right hepatectomy involves the resection of segments IV through VIII. Extended left hepatectomy involves the resection of segments II through V plus VIII. Again, either of these extended resections may or may not include resection of segment I, which should be stipulated.

Right anterior sectorectomy includes segments V and VIII. Right posterior sectorectomy includes segments VI and VII. Left medial sectionectomy removes segment IV. Left lateral sectionectomy includes segments II and III. A segmentectomy involves the resection of a single segment and a bisegmentectomy involves the resection of two contiguous segments.

10 The steps involved in each of these major hepatectomies include optimal exposure of the liver, vascular inflow control, vascular outflow control, and parenchymal transection. Vascular inflow control can be obtained by directly ligating the main right or left branches of the hepatic artery and portal vein in the hilum or by intermittent 10- to 20-minute intervals of a Pringle maneuver with 3 minutes in between to reestablish blood flow (or both). It is the author's preference to encircle the hepatoduodenal ligament twice with a quarter-inch Penrose drain that is tightened and clamped for a Pringle maneuver. Pedicle ligation can also be performed, as described previously, or the pedicles can be controlled as they are encountered during parenchymal transection. It is the author's preference to obtain vascular inflow by ligating the appropriate vessels in the hilum or by pedicle ligations and to supplement this with intermittent Pringle maneuvers, as necessary, during parenchymal transection. Often the Pringle maneuver is not required, but if bleeding from inflow vessels becomes significant, then it should be performed. Vascular outflow to the right or left liver can be obtained by exposing and ligating the hepatic veins, as previously described, or by ligating the vessels intraparenchymally during transection of the liver tissue. Parenchymal transection can be performed using a multitude of techniques including finger fracture, using a Kelly clamp to fracture, Cavitron Ultrasonic Surgical Aspirator (CUSA), harmonic

FIGURE 56.22. Hepatotomies to access pedicles for ligation: right hepatectomy, 1 and 2; left hepatectomy, 3 and 5; right anterior sectorectomy, 2 and 4; and right posterior sectorectomy, 1 and 4. (From Fong Y, Blumgart LH. Useful stapling techniques in liver surgery. *J Am Coll Surg* 1997;185:93–100, with permission.)

FIGURE 56.23. Caudal retraction of the left hepatic lobe with division of middle and left hepatic veins during left hepatic lobectomy. Often, the division of the middle and left hepatic veins is intraparenchymal.

scalpel, stapling devices, electrocautery devices with or without saline perfusion, high-pressure water jets, and radiofrequency planar arrays. The superiority of any one of these techniques has not been established, and all are used. With these techniques, individual blood vessels and bile ducts are cauterized, clipped, or sutured in rapid succession as they are encountered. Constant reevaluation of the direction of transection is important both to not injure vital structures to the remnant liver and to maintain a negative margin. After parenchymal transection and removal of the specimen, the raw surface of the liver is carefully inspected for bleeding and bile leakage, which can then be controlled by suture ligation and the use of argon beam coagulation. The author's preference is to selectively use closed suction drains near resected liver surfaces to monitor and drain unrecognized postoperative bile leaks. Some centers have decreased the use of closed suction drains in favor of radiologic intervention when necessary, because they often clog or do not actually drain the fluid collections that form.

FIGURE 56.24. A vascular endoscopic stapling device is used to divide the right hepatic vein after the right side of the liver has been mobilized. (From Fong Y, Blumgart LH. Useful stapling techniques in liver surgery. *J Am Coll Surg* 1997;185:93–100, with permission.)

SEGMENTAL RESECTIONS

To maximize functional reserve, (multi)segmental or subsegmental (or nonanatomic) hepatectomies can be performed. For example, left lateral sectionectomy (segments II and III), central hepatectomy to remove the right anterior section (segments V and VIII) and left medial section (segment IV), right posterior sectionectomy (segments VI and VII), or caudate resection (segment I) are examples in which one, two, or three contiguous segments are removed to eradicate tumors within those regions of the liver. These resections are often done with intermittent Pringle maneuvers until the specific pedicles supplying these areas are controlled.

CHAPTER 57 ■ HEPATIC INFECTION AND ACUTE HEPATIC FAILURE

ARUNA SUBRAMANIAN, AHMET GURAKAR, ANDREW KLEIN, AND ANDREW CAMERON

KEY POINTS

- 1 Gram-negative anaerobes account for two thirds of the cases of pyogenic liver abscesses, with anaerobes isolated in 30% of cases.
- 2 First-line treatment of hepatic amebic abscesses is oral metronidazole, with percutaneous drainage considered if there is a poor response to therapy or when superinfection is suspected.
- 3 The treatment of choice for hydatid cysts is surgical resection of the intact cyst, often preceded by injection of ethyl chloride, 95% ethanol, or 20% sterile saline solution. Surgery should occur after antiparasitic medication has begun.
- 4 Viral hepatitis, especially hepatitis B and C, represents a principal cause of chronic liver disease, cirrhosis, and hepatocellular carcinoma in the United States and worldwide.
- 5 Liver transplantation is the treatment of choice for patients with liver failure resulting from viral hepatitis, although recurrence of viral infection in the allograft is universal with hepatitis C virus.
- 6 About one third of patients with acute liver failure will die without liver transplant, usually secondary to cerebral edema and sepsis, with 25% of patients surviving with medical treatment and 40% undergoing transplantation.

PYOGENIC LIVER ABSCESS

Liver abscesses are broadly categorized as either pyogenic (of bacterial origin) or amebic (caused by *Entamoeba histolytica*). Pyogenic liver abscesses are infrequent, with an estimated incidence of 2.3 per 100,000 population, and a peak incidence in the fifth and sixth decades of life.¹ However, they are potentially lethal and outcomes correlate directly with prompt diagnosis and rapid intervention.

Over the past century, the pathogenesis of liver abscesses has changed. A classic study by Ochsner in the 1930s, prior to the introduction of antibiotics, reported that appendicitis and other intra-abdominal infections were the most frequent cause of pyogenic liver abscess. The route of infection was attributable to the portal vein in 43% of instances, whereas the biliary tree was the source of infection in only 14% of cases. Over the past 20 years, invasive procedures involving the liver, biliary tree, and pancreas have resulted in an increased incidence of pyogenic liver abscesses. Currently, cholangitis is the major cause of pyogenic liver abscess, due to obstruction from biliary malignancies and stone disease. The use of stents to treat both malignant and nonmalignant strictures is also a contributing factor. The portal vein serves as the conduit for infection from intraperitoneal sources in a minority of cases, and appendicitis has been replaced as the most frequent intraperitoneal source by infections associated with diverticulitis, perforated cancers, perforated ulcers, and inflammatory bowel disease. Hepatic abscesses that occur following liver transplantation should raise concern for the presence of hepatic artery thrombosis (Fig. 57.1). Direct extension from a contiguous source of infection can occur with cholecystitis, subphrenic abscess, or perinephric abscess. Fewer than 5% of pyogenic liver abscesses are due to trauma, and 20% to 40% are considered cryptogenic. Most pyogenic abscesses are solitary and polymicrobial and involve the right lobe of the liver. Abscesses in liver metastases usually result from superinfection of a central area of necrosis. Hepatic abscesses may be further complicated by rupture into the peritoneum or retroperitoneum, pleuropulmonary fistulas, rupture into the pericardial cavity, rupture

into the gastrointestinal tract, and involvement of surrounding blood vessels.²⁻⁴

Individuals over 50 years of age, males, liver transplant patients, diabetics, and those with malignancies are at highest risk for pyogenic liver abscesses. Fever is the most frequent presenting symptom, often without other localizing signs and symptoms. Right upper quadrant pain, chills, anorexia, weight loss, malaise, jaundice, and weakness are usually present. Hepatomegaly is less frequent than in amebic abscesses.^{1,2,4}

Laboratory studies show leukocytosis in approximately 70% of patients. Elevated serum bilirubin, elevated alkaline phosphatase, elevated transaminases, or low albumin levels are observed in approximately 50% of all cases.^{2,3}

Chest radiographs are abnormal in half of patients with pyogenic liver abscesses, reflecting an underlying inflammatory process. The most frequent findings include a right pleural effusion, elevation of the right hemidiaphragm, and atelectasis of the base of the right lung. Gas within the abscess may be seen in 10% to 20% of patients. Ultrasound evaluation is diagnostic in over 90% of cases. Advantages are that it is rapid, is radiation-free, can differentiate solid from cystic structures, is easy to perform, and can guide percutaneous drainage. Disadvantages are that it is operator dependent and has a degree of resolution inferior to that of other imaging techniques. Computed tomography (CT) scanning is probably the most reliable diagnostic modality. In contrast-enhanced CT imaging, small abscesses appear as hypoattenuated areas with faint rim enhancement and surrounding edema that distinguishes them from hepatic cysts. Magnetic resonance imaging (MRI) is frequently used but somewhat limited by its cost. T2-weighted images show slightly increased signal intensity associated with perilesional edema. Cholangiography (percutaneous or endoscopic) can define the anatomy of both the biliary tree and the hepatic abscess in about two thirds of cases. It is associated, however, with potential septic flares despite the administration of antibiotics due to disturbance of the bacterial flora.^{2,5,6}

- 1 Gram-negative aerobes are encountered in two thirds of patients. Among these pathogens, *Escherichia coli*, *Klebsiella*

FIGURE 57.1. Computed tomogram of a pyogenic hepatic abscess in a liver transplant recipient with occlusion of the hepatic artery.

pneumoniae, and *Proteus* species are the ones most frequently isolated. These bacteria are frequently accompanied by enterococci in abscesses arising from a biliary source; anaerobes accompany the gram-negative aerobes when there is a colonic or pelvic source. Anaerobes (such as *Bacteroides fragilis*) are found in 30% of cases. Streptococci, including aerobic and anaerobic forms, are present in approximately one third of patients. Approximately 60% of patients have concordant results of blood and abscess cultures, and blood cultures should be obtained prior to antibiotic administration. Broad-spectrum antibiotics aimed at gram-negative aerobes, streptococci, and anaerobes are indicated until bacterial sensitivities have been clearly identified. A frequently used antibiotic combination is ampicillin, an aminoglycoside, and metronidazole. The ampicillin and aminoglycoside can be replaced with a third-generation cephalosporin (e.g., ceftriaxone) in patients at risk for renal toxicity, and those with β -lactam intolerance can be treated with a fluoroquinolone plus metronidazole. In instances of mixed pyogenic and fungal abscesses, antifungal agents should be considered early. Overall, the duration of the treatment should be based on clinical response, toxicity of the regimen, and characteristics of the abscesses. Intravenous antibiotics are usually administered for 14 days, followed by oral agents for a total of 6 weeks.^{2,3,7-9}

In the past, surgical drainage was the treatment of choice. Currently, percutaneous drainage is considered the standard therapy. Its use, however, may be limited or contraindicated by the presence of ascites, multiple abscesses, a transpleural drainage route, large size of the abscess, and the presence of an intra-abdominal source requiring an open approach. Unless appropriate therapy is started as soon as the diagnosis is made, death is the usual outcome. Reported mortality ranges from 2.5% to over 30% and is highest in patients with multiple abscesses, with non-*K. pneumoniae* pathogens, with mixed bacterial and fungal abscesses, with respiratory symptoms, and with abscesses 5 cm or greater in diameter.^{2,3,7,10,11}

AMEBIC LIVER ABSCESS

Amebic liver abscesses are caused by *E. histolytica*, a non-flagellated pseudopod-forming protozoan. Amebiasis is

most prevalent in tropical and subtropical regions with poor sanitation, and it is estimated that 40 million to 50 million people are infected annually worldwide. In the United States, the highest incidence of infection is encountered in immigrants from and travelers to endemic areas. Most infection is asymptomatic, but amebic dysentery, amebic liver abscesses, and, rarely, pulmonary, cardiac, or brain involvement can occur. Hepatic abscesses occur in only 3% to 7% of individuals with amebiasis. The peak incidence of amebic abscesses is observed in patients in their third or fourth decade of life. Men are affected 7 to 10 times more frequently than women, and corticosteroid use is a risk factor for invasive amebiasis.^{2,12}

Fecal-oral transmission is the most frequent route of infection. Ingested cysts, containing four nuclei, pass unaltered through the stomach and reach the intestine. Once in the intestine, the cyst wall is degraded by trypsin and eight trophozoites are released. These infective forms multiply in the colonic lumen, especially in the cecum. While living within the colonic lumen, *E. histolytica* may become tissue invasive. Invasion may range from superficial mucosal ulceration to perforation. Amebic trophozoites that enter the mesenteric veins or lymphatics reach other organs. The portal vein is the route via which they reach the liver, the most frequent site of extraintestinal involvement. Amebic trophozoites cause obstruction of venules, thrombosis and infarction of the corresponding areas of hepatic parenchyma, and eventually abscesses (Fig. 57.2). In the distal colon they become cystic, undergo two consecutive divisions, are excreted in the feces as tetranucleate cysts, and remain viable for 8 to 30 days after being shed. Cysts are susceptible to acetic acid, iodine, chlorine, and temperatures greater than 68°C.^{2,6,12}

Liver abscesses range in size from several millimeters to gigantic masses (Fig. 57.3). Differential diagnosis is with pyogenic abscess and malignancies. Abscesses are encountered more frequently in the right lobe and tend to be single lesions. Amebic abscesses show slight inflammation on the periphery, and many times contain a dark hemorrhagic fluid known as “anchovy paste” (Fig. 57.4). Patients most frequently present with fever and right upper quadrant abdominal pain. Other findings include hepatomegaly, weight loss, diarrhea, chills, and afternoon and night sweats. Jaundice is less frequent than in pyogenic abscesses. Abscesses have been classified into acute

FIGURE 57.2. Amebic abscess of the liver. A photomicrograph of the margin of an amebic abscess shows fibroblastic proliferation surrounding the cavity and amebic trophozoites in the lumen. FIGURE 57.3. Sonogram (A) and computed tomogram (B) in a patient with multiple amebic abscesses (arrows).

or chronic and benign or aggressive. The most feared complication is rupture into surrounding tissues or spaces. Bacterial superinfection of initially amebic abscesses may occur.^{1,2,4,6,12-14}

Most patients with amebic abscesses have elevated white blood cell counts with no eosinophilia. Serum alkaline phosphatase is elevated in approximately 75% of cases. Hypoalbuminemia may be seen, and serum bilirubin and transaminase levels are slightly elevated. *E. histolytica* is not found in fecal specimens of most patients with hepatic abscesses. Antibodies in serum are encountered in 92% to 99% of patients with amebic liver abscesses and are detectable 7 to 10 days after the appearance of symptoms. Indirect hemagglutination and enzyme-linked immunosorbent assay (ELISA) have reported sensitivities of 99% and 97.9% and specificities of 99.8% and 94.8%, respectively. Other available diagnostic tests include indirect immunofluorescence, latex agglutination, complement fixation, gel diffusion, and counterimmunoelectrophoresis. Gel diffusion and counterimmunoelectrophoresis remain positive for only 6 to 12 months after infection and are used to distinguish current from previous infection.^{2,12,15}

Chest radiographs are abnormal in the majority of patients with amebic hepatic abscesses. Findings include elevation of the right hemidiaphragm, right pleural effusion, atelectasis in the region of the base of the right lung, and a right pleural effusion. CT scanning is probably the imaging technique of choice, given the detailed information it provides. An enhancing wall and surrounding edema are usually observed in contrast-enhanced CT scans. Ultrasonography is very useful as well, but its accuracy is associated with the skills of the operator, is influenced by physiologic changes such as hepatic steatosis, and has a resolution inferior to that of CT scans. Amebic abscesses usually lack wall echoes by ultrasound. MRI shows homogeneous low signal intensity on T1- and high signal intensity on T2-weighted images. Technetium Tc99m nuclear scanning displays a photopenic area. Gallium scanning shows amebic abscesses as cold spots, because they do not contain leukocytes, which may aid in differentiating them from pyogenic abscesses.^{2,6,12}

2 Treatment of hepatic amebic abscesses is based on amebicidal drugs. Metronidazole is the drug of choice. Standard dosing is 750 mg orally three times daily or 500 mg intravenously every 6 hours for 7 to 10 days, with oral administration being the preferred route. Metronidazole has been shown to effectively treat both intestinal and extraintestinal sites. In patients who are slow to respond to therapy or with relapsed disease, a prolonged course of metronidazole may be considered, or a nitroimidazole with a longer half-life (e.g., tinidazole) can be given at a dose of 2 g for 3 days. Following therapy for invasive amebiasis, a luminal agent must be given, such as paromomycin for 10 days or iodoquinol for 20 days. Amebic liver abscesses can almost always be treated with medical therapy alone. Percutaneous drainage is considered in cases of poor response to antiamebic agents, when superinfection is suspected, or when there is a risk of rupture. Open surgical drainage is almost never required and is recommended only in severe, complicated cases.^{2,12,13}

ECHINOCOCCUS (HYDATID DISEASE)

Hydatid disease, caused by *Echinococcus granulosus*, *E. multilocularis*, and *E. vogeli*, is endemic in the Mediterranean basin and other regions with sheep-rearing economies but rare in the United States. *E. granulosus* is the species that most frequently results in liver involvement. Dogs are the definitive host, although the disease is endemic

FIGURE 57.5. A partly opened hepatic hydatid cyst. Brood capsule and daughter cysts are visible in the cavity. (Reproduced with permission from Kean BH, Sun T, Ellsworth RM. *Color Atlas/Text of Ophthalmic Parasitology*. New York: Igaku-Shoin; 1991:188.)

in sheep and cattle farming regions. The life cycle of the organism is complete when the definitive host ingests infected viscera, and scoleces released in the intestine develop into adult worms. Humans are intermediate hosts and acquire echinococcal eggs by either ingestion of contaminated foods or contact with infected animals. The egg is digested in the duodenum and yields an embryo (oncospheres). Embryos invade the intestinal wall and reach the liver via the portal vessels. Although many embryos are destroyed in the liver, those that survive lodged in capillaries develop into hydatid cysts. The most frequent site of hydatid cysts is the liver (50% to 77% of cases), followed by the lungs (10% to 40% of cases).^{6,16–18}

E. granulosus and *E. vogeli* cause liver cysts, while *E. multilocularis* is associated with tumorlike lesions or alveolar disease. Liver involvement may lead to venous obstruction, portal hypertension, sepsis, and cholangitis. Hydatid cysts are fluid filled and round and contain three layers of host tissue: an outer 2- to 4-mm-thick fibrous *pericyst* composed of compressed and fibrotic liver tissue, a 2-mm-thick middle anuclear hyaline layer or *ectocyst*, and an *internal germinal layer* or *endocyst* derived from the parasite. As the cyst matures, invagination of the germinal layer leads to development of daughter cysts in the periphery (Fig. 57.5). Calcifications may be observed in both viable and nonviable cysts.^{6,17,18}

Cysts have an annual growth rate of 1 to 3 cm in diameter. Symptoms are caused by enlarging cysts that lead to abdominal pain (the most common presenting symptom), biliary obstruction, jaundice, and, rarely, portal hypertension. The only typical clinical finding of hepatic hydatid cyst is a palpable hepatic mass. Involvement of the biliary tree is seen in 12% to 80% of cases. Biliary findings may occur either as a result of communication between the pericyst and the biliary ducts or due to rupture of the cyst into the biliary tract. Fistulous communication of the cyst and bile ducts may be associated with secondary bacterial infection of the cyst, cholangitis, or biliary obstruction. Bacterial contamination occurs in 10% to 35% of cases. Occasionally, cysts spontaneously rupture into the peritoneal cavity and cause abdominal pain and anaphylaxis. Multiple intra-abdominal cysts may develop as a result of intraperitoneal leakage. Hepatic hydatid cysts may perforate the diaphragm and lead to

empyema, pulmonary cysts, biliary-bronchial fistulas, or pericardial collections.¹⁹

Routine laboratory tests in patients with hydatid cysts may be normal or nonspecifically abnormal (e.g., showing features of obstructive jaundice). Eosinophilia is frequently present. Serologic screening tests (e.g., indirect hemagglutination, latex agglutination, ELISA) based on crude antigens are associated with high rates of false-positive and false-negative results. However, ELISA detection of specific antigens and immune complexes of the cyst has a much higher sensitivity, while ELISA and radioallergosorbent test (RAST) can also detect specific IgE antibodies. Antigen 5 (arc-5) and antigen B8 are the parasitic antigens of major diagnostic value. Confirmatory arc-5 immunoelectrophoresis has a reported positive rate of over 90%. Purified fractions enriched in antigens 5 and B8 and glycoproteins from hydatid fluid are reported to have sensitivity and specificity rates of 95% and 100%, respectively. Serology is less likely to be positive when the cyst is calcified or nonviable.^{6,16}

Hydatid cysts have a typical appearance on imaging studies. Furthermore, imaging studies are useful in detecting associated complications. Ultrasound images may show daughter cysts, peripheral calcifications, or the so-called water lily sign of curved bands of delaminated endocyst. On CT scans, hydatid cysts are usually seen as hypoattenuating lesions. Daughter cysts are visualized in approximately 75% of cases and calcifications within the surrounding cyst wall in 50% of cases. MRI is the technique that best demonstrates pericyst, matrix or “hydatid sand” (free scoleces), and daughter cysts. The fibrous and calcified pericyst appears as a hypointense ring on both T1- and T2-weighted images. The hydatid matrix is hyperintense on T2-weighted images and hypointense on T1-weighted images. Daughter cysts are hypointense on both T1- and T2-weighted images. Endoscopic retrograde cholangiopancreatography (ERCP) is especially useful in cases involving the bile ducts.^{6,16}

Open surgical resection is classically the treatment of choice in cases of symptomatic or complicated hepatic cysts (Fig. 57.6). The goals of surgery are to remove the cyst intact (without spillage of the internal contents) and to obliterate the cyst cavity; surgical resection lowers the rate of recurrence. Alternative methods have been developed, however. One of them is to aspirate the cyst contents after the operative field has been protected to prevent any potential contamination should spillage of the cyst contents occur. In cases in which the aspirate is clear, ethyl alcohol or 20% sterile

FIGURE 57.6. The external surface of the liver of a patient with echinococcosis before operation. (Reproduced with permission from Sun T. *Parasitic Disorders: Pathology, Diagnosis, and Management*, 2nd ed. Baltimore, MD: Lippincott Williams & Wilkins; 1999.)

saline solution is injected to kill remaining scoleces. The cyst contents and pericystic wall are subsequently removed. In cases in which the aspirate is bilious and a communication with the biliary tree is suspected, the cyst is resected without injecting alcohol to prevent sclerosing cholangitis. Laparoscopic resections have also been reported. A percutaneous technique referred to as PAIR (puncture, aspiration, injection, reaspiration) simultaneously with albendazole therapy has been employed successfully and found to have several advantages over surgical resection. In this modality, after ultrasound-guided percutaneous puncture and aspiration of the hydatid cyst, 20% sodium chloride solution or 95% ethanol is injected into the cavity and subsequently reaspirated. Therapy with albendazole and/or mebendazole is not usually a curative approach by itself but should precede and follow the resection whenever possible. Recent studies report postoperative morbidity and mortality rates of 3% to 24% and 0% to 4%, respectively. Recurrence rates after surgery or invasive procedures range from 0% to 15% and are usually associated with residual vesicles or spillage of hydatid cyst contents.^{16–23}

SCHISTOSOMA

Schistosomiasis constitutes a health risk for inhabitants of endemic regions as well as for visitors to these sites. *Schistosoma mansoni*, *S. japonicum*, and *S. hematobium* are the species of this trematode fluke that most frequently infect humans. Liver disease, although encountered with all species, is especially severe with *S. mansoni*, *S. japonicum*, and *S. mekongi*. Endemic areas where these trematodes are encountered are also frequently associated with a high prevalence of hepatitis B and C. The life cycle of *Schistosoma* species alternates between sexual reproduction in humans and asexual multiplication in water snails. Cercariae enter the human host by penetrating the skin. An irritating maculopapular rash that lasts for several days is one of the early manifestations. Schistosomes live in the intestinal lumen. Eggs reach the liver via the portal circulation and cause an inflammatory reaction.^{17,18,24}

Infection is characterized by the presence of inflammatory granulomata surrounding schistosomal eggs. Acute schistosomiasis is seen most frequently in nonimmune visitors to endemic areas. Inflammatory hepatic schistosomiasis causes hepatomegaly and severe splenomegaly, usually in children and adolescents. With very intense egg infestation, it can lead to widespread granulomatous necrosis of the liver and even death. In contrast, chronic schistosomiasis is seen in young and middle-aged adults. It is usually asymptomatic until variceal hemorrhage occurs as a result of presinusoidal portal hypertension. These patients exhibit hepatosplenomegaly, no ascites, and relatively normal hepatic synthetic function. Hepatomegaly involves mainly the left lobe. Severe decompensation tends to be observed in cases where schistosomal infections and viral hepatitis coexist. Hepatocellular carcinoma, colon cancer, and follicular lymphoma of the spleen have been reported in association with hepatic schistosomiasis.^{6,17,18,25,26}

Active infection is usually diagnosed by the presence of schistosomal eggs in the stool (Kato-Katz smears), epidemiologic data, and biochemical or serologic findings. Laboratory features include eosinophilia, hypoalbuminemia, hypergammaglobulinemia, and elevated serum alkaline phosphatase. Serum transaminase levels are usually normal. ELISA serum antibody tests are highly sensitive but may not correlate with activity of the infection. Histologically, heavy infection can lead to prominent granulomata formation, normal liver architecture, and severe portal fibrosis (Symmers pipestem fibrosis). In mild infections small white granulomata, each with a schistosomal egg at its center, are observed throughout the liver (Fig. 57.7). The hepatic parenchyma is darker than usual as a

FIGURE 57.7. Hepatic schistosomiasis. A hepatic granuloma surrounds a degenerating egg of *Schistosoma mansoni*. (Reproduced with permission from Rubin E, Farber JL. *Pathology*, 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 1999.)

result of regurgitated heme-derived pigments from the schistosome gut.^{6,17,18,26}

Imaging studies are not useful in the diagnosis of acute infection. Ultrasound examination in chronic *S. mansoni* infection shows echogenic thickening of the wall of the portal vein and its branches, in a bull's-eye pattern. Hypertrophy of the left hepatic lobe, splenomegaly, and engorged venous collaterals are also observed. On noncontrast CT scan the fibrosis around the portal vein branches presents as low-attenuation rings throughout the liver. Administration of intravenous contrast material leads to marked enhancement of the lesions. The periportal bands appear isointense on magnetic resonance T1-weighted images and hyperintense on T2-weighted images.⁶

The preferred treatment of schistosomiasis is administration of praziquantel, though this is ineffective in early infection. The reported cure efficacy is approximately 90%. It is essential that patients with chronic schistosomiasis undergo evaluation and treatment of esophageal varices.^{17,18}

VIRAL HEPATITIDES

- 4 Viral hepatitis represents a principal cause of chronic liver disease, cirrhosis, and hepatocellular carcinoma. Infection is pandemic in the United States and worldwide, representing one of the significant global public health problems of our time.
- 5 Hepatitis C virus (HCV) has become the most common indication for liver transplant in the United States and recurrent HCV disease after transplant is a major unmet challenge in the field. Liver transplant for hepatitis B, in distinction, has shown greatly improved results in recent years due to improved pharmacologic treatment options.

The pathophysiology of liver injury is largely host response to noncytotoxic virus. Table 57.1 summarizes the characteristics of the five viruses most commonly associated with clinical hepatitis, their modes of transmission, and the consequences of infection.

Hepatitis G virus (HGV) does not appear to be injurious to the liver and will not be considered further. Other viral infections can produce acute hepatitis in a fraction of patients (e.g., Epstein-Barr virus, cytomegalovirus, herpes simplex virus, and varicella virus). In some cases the hepatitis caused by these viruses generally associated with more systemic illness may be severe, and in fact liver involvement may be the dominant component of the infected patient's illness.

TABLE 57.1

CLASSIFICATION OF VIRAL HEPATITIS

■ VIRUS	■ THE VIRAL HEPATITIDES				
	■ HEP A PICORNAVIRUS (RNA)	■ HEP B HEPADNAVIRUS (DNA)	■ HEP C FLAVIVIRUS (RNA)	■ HEP D VIROID (RNA)	■ HEP E CALICIVIRUS (RNA)
Transmission	Fecal-oral	Parenteral	Parenteral	Parenteral	Fecal-oral
Acute disease	Common	Common	Uncommon	Common	Yes
Evolution to chronic disease	Never	Infrequent in adults	Frequent (70%)	Yes	Described in organ transplant recipients
New cases/year	180,000	180,000	40,000	Unknown, found in approximately 5% of cases of HBV infection	300
# Infected (U.S.)	—	1,250,000	4,000,000		Unknown, uncommon
Worldwide	—	350,000,000	170,000,000		
Treatment	None	Lamivudine Adefovir Entecavir	Interferon + Ribavirin	Treatment of HBV	Mainly sanitary preventative
Prophylaxis	Vaccine and Ig	Vaccine and Ig	None	Vaccinate against HBV	In development
Fulminant failure	Rare	Yes	Never	With HBV, as coinfection or superinfection	Especially in pregnant women

HBV, hepatitis B virus; Hep, hepatitis; Ig, immunoglobulin.

HEPATITIS A VIRUS**Molecular Structure**

Hepatitis A virus (HAV) was identified in 1973.²⁷ HAV belongs to the Picornaviridae family, genus Hepatovirus. Four distinct genotypes have been identified, though no clinical difference between them has been appreciated and all four genotypes belong to a single serotype.²⁸ HAV is a single-stranded RNA virus. It is 27 nm in diameter and nonenveloped. The viral genome is 7,474 nucleotides in length and is divided into 5' and 3' untranslated regions and a single long open reading frame that encodes a 2,227-amino-acid polypeptide. Upon processing this peptide yields four structural and seven non-structural proteins.

Epidemiology/Risk Factors for Transmission

Hepatitis A disease has been long known (*epidemic jaundice*, *catarrhal jaundice*, *campaign jaundice*) and continues to occur worldwide. The incidence in the United States has declined with effective vaccination but remains around 1.2 per 100,000.²⁹

The major mode of transmission is fecal-oral spread and is more common in lower socioeconomic areas where sanitation is poor. Common risk factors in the United States are international travel, especially to Mexico or Central/South America; household contact with another infected with HAV; homosexual activity in men; foodborne or waterborne outbreaks; children in daycare centers; and injection drug use. Humans are the only host for HAV infection, and the only organ injured is the liver.

Community outbreaks due to contaminated food have been described.^{30,31} Contaminated shellfish and green onions have

been implicated in several outbreaks, as have frozen strawberries.

Clinical Features

Hepatitis A infection almost universally results in an acute self-limited illness and can produce either icteric or anicteric syndromes (Fig. 57.8). The incubation period is 28 days. The anicteric prodrome lasts from 2 days to 3 weeks and typically consists of fatigue, malaise, nausea, vomiting, anorexia, fever, and right upper quadrant pain; the diagnosis of hepatitis may be missed when it does not progress to jaundice. In cases where jaundice becomes manifest, it persists for 1 to 6 weeks. Transaminase levels are usually above 1,000 IU/mL and serum bilirubin (>10 mg/dL) and alkaline phosphatase values are elevated as well. Serum IgM antibodies are detected in 95% of patients and are the “gold standard” of diagnosis. IgG antibodies become elevated as jaundice subsides and may persist for years.

HAV infection leads to fulminant liver failure in 0.01% to 0.35% of cases of acute hepatitis A. This rare event mostly occurs in patients with underlying liver disease, especially hepatitis C and less commonly hepatitis B or alcoholic liver disease. The risk of fulminant failure is also higher in people over 40 years of age, intravenous drug users, homosexual men, and inhabitants of endemic areas.³²

Treatment

Most patients with HAV infection recover with supportive care (approximately 20% require hospitalization in large outbreaks). Hygiene should be a top priority to prevent spread of

FIGURE 57.8. Clinical course of hepatitis A infection.

the virus, because fecal shedding of the virus occurs prior to the onset of symptoms and jaundice. Spontaneous survival in cases of acute liver failure may be as high as 50%. Liver transplantation is indicated in cases in which recovery is unlikely. Recurrence of HAV infection in the allograft may occasionally be encountered. This has led some to recommend administration of immunoglobulin in such instances.^{32,33}

A formalin-inactivated HAV vaccine was found to be safe and to induce an immune response in almost all recipients after two doses. Vaccination as recommended by the Advisory Committee on Immunization Practices of the Centers for Disease Control and Prevention (CDC) includes children 2 years of age or older in states or counties with high rates of infection (20 or more cases per 100,000 population from 1987 to 1997) as well as high-risk persons 2 years of age or older. Immune globulin, administered intramuscularly at a dose of 0.02 mL/kg of body weight within the first 14 days after exposure, prevents disease in more than 85% of cases. Close contacts of patients with recent onset of the illness, people exposed to contaminated foods, and selected travelers to endemic areas benefit the most.³⁴

HEPATITIS B VIRUS

Molecular Structure

Hepatitis B virus (HBV) is a DNA virus that belongs to the hepadnavirus family. It is the smallest DNA virus with the ability to infect humans. HBV virions are 40 to 42 nm in diameter, with a double shell and an outer lipoprotein envelope. The viral nucleocapsid, or core, contains a 3.2-kb partially duplex DNA and a polymerase. Replication resembles that of retroviruses, in which the viral DNA polymerase acts as a reverse transcriptase. The HBV polymerase lacks proofreading activity. This finding is associated with an estimated frequency of 10^5 to 10^6 mutations per nucleotide per year and the resultant development of mutant forms of the virus.³⁵⁻³⁷

Epidemiology/Risk Factors for Transmission

It is estimated that 350 million people are infected with HBV worldwide. Transmission is usually via nonsterile needles, intimate contacts, and blood transfusions. Infection by vertical transmission from mother to child is a serious problem in

the developing world. There are no known animal reservoirs or evidence that insects are involved in transmission of the disease.

The hepatitis B virus replicates mainly in hepatocytes but is not itself cytotoxic. Hepatocyte injury is due to the resultant host immune response.

Clinical Features

The incubation period in cases of acute infection is approximately 8 weeks. The presence of serum hepatitis B surface antigen (HBsAg) may precede the clinical onset of jaundice. Acute infection is associated with serum HBV DNA, HBV DNA polymerase, hepatitis B early antigen (HBeAg), and liver HBV DNA and hepatitis B core antigen (HBcAg). HBeAg is a useful marker of viral replication, except in individuals infected with mutant viruses where it may be undetectable despite active viral replication (Fig. 57.9). In such circumstances, serum HBV DNA is detected by hybridization techniques. Serum anti-HBc IgM becomes detectable with the onset of jaundice. In most individuals, when HBV does not develop into chronic hepatitis, anti-HBc IgM becomes undetectable beyond 6 months. On occasion, however, it may persist for years after the acute infection or may recur as an amnestic phenomenon in reactivating chronic hepatitis B, thus limiting its usefulness as a marker of acute hepatitis B infection.

Although HBV accounts for 40% of cases of acute liver failure in developing countries, it is estimated that the incidence in the United States is approximately 10%. Hepatitis B becomes fulminant in approximately 1% of acute cases. Women, elderly individuals, and those who sustain superinfection with another virus (such as HCV) seem to be at greater risk. Furthermore, the risk of acute liver failure is directly proportional to the antibody titers to HBcAg and HBsAg. Some cases of acute liver failure may be due to reactivation of HBV in patients with chronic infection. In cases of reactivation, reappearance of HBc IgM antibodies (Abs) aids in the diagnosis. Spontaneous survival after HBV acute liver failure ranges from 15% to 36%.^{38,39}

Most patients with acute HBV infection in the Western world (low carrier rates) recover completely. Approximately 25% of adult cases in the Western world develop clinical jaundice but do

FIGURE 57.9. Clinical course of acute hepatitis B infection.

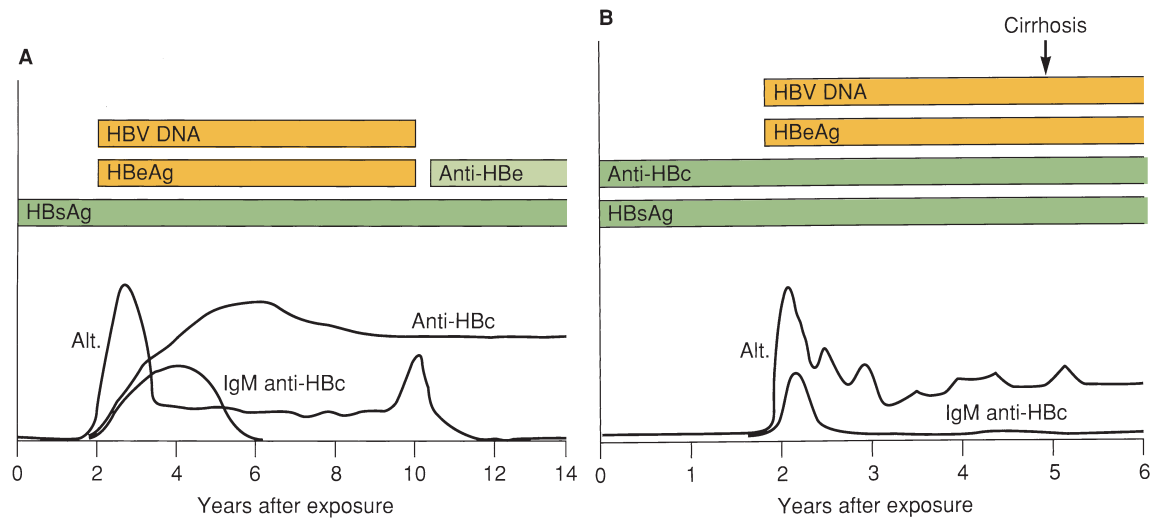

FIGURE 57.10. Clinical course of chronic hepatitis B. **A:** A benign chronic carrier has continued production of hepatitis B surface antigen but there is an absence of serum markers of viral replication. **B:** A pattern of continuing liver injury and serum markers of active viral replication.

not become HBV carriers. They usually retain HBcAb and HBsAb markers with no detectable HBsAg or HBV DNA. Approximately 10% of Western adults with acute HBV infection become chronic carriers, as determined by the presence of HBsAg in serum for more than 6 months (Fig. 57.10). Most HBV carriers have a benign state, with HBV DNA sequences integrating into their native genome. Histologically, these individuals show hepatocytes with ground-glass appearance resulting from cytoplasmic accumulation of HBsAg proteins. Portal triad inflammation may or may not be present. The remainder of HBV carriers develop ongoing liver injury and usually have detectable HBeAg or HBV DNA and have free episomal HBV sequences in addition to the ones integrated into their native genomes. Histologically, there is evidence of active inflammation.

In Western Europe and North America, the overall incidence of chronic infection is less than 1%. It is estimated that there are 1 million deaths each year as a result of cirrhosis and hepatocellular carcinoma associated with chronic hepatitis B worldwide. Cirrhosis develops in 10% to 30% of individuals with evidence of active viral replication within 5 years and is especially high in patients infected early in life, with persistent seropositivity for HBeAg or with increased serum alanine aminotransferase (ALT) levels after HBeAg seroconversion. Although imperfect, twice-a-year screening with hepatic ultrasound and/or α -fetoprotein levels to detect early hepatocellular cancers is recommended for chronically infected patients.^{36,37,40}

Treatment

Primary prevention by means of vaccination constitutes the best treatment approach for HBV infection. Individuals at high risk include health care workers, visitors to highly endemic areas, sexual contacts of chronic carriers or acutely infected people, and household contacts of those at high risk of infection (intravenous drug users, hemophiliacs, patients with thalassemia). The hepatitis B vaccine is given as a series of three intramuscular doses and has an almost 100% efficacy among immunocompetent persons with antibody levels of at least 10 mIU/mL. Since the World Health Organization in 1991 called for all children to receive the vaccine, 116 countries have adopted it as a routine immunization. Hepatitis B

immune globulin has a reported efficacy of 85% to 95% in the prevention of newborn infections and approximately 75% in cases of needle sticks or sexual infections in people exposed to the virus with no previous HBV immunity. It should be administered as soon as possible after exposure (for perinatal cases within 24 hours after birth, for needle sticks within 7 days, and for sexual exposures within 14 days) together with the first dose of the hepatitis B vaccine series. Additional doses of the vaccine should follow according to the regular schedule. Testing for HBsAg is warranted in pregnant women to reduce the risk of vertical transmission.³⁵

Therapy is usually directed at HBeAg-positive cases that have an increased risk of cirrhosis and hepatocellular carcinoma. It seems that HBeAg-negative patients with viremia of greater than 10^5 molecules per milliliter and liver dysfunction may also benefit from antiviral therapy. At present, antiviral therapy is not offered to asymptomatic HBeAg-negative chronic carriers with viral loads under 10^5 molecules per milliliter and normal alanine aminotransferase values. Therapeutic success in HBeAg-positive cases is determined by seroconversion to HBeAb and reduction of viral loads. Cure of infection as determined by loss of HBsAg and absent viremia by polymerase chain reaction (PCR) analysis is achieved in only 1% to 5% of cases. Patients with chronic hepatitis B and cirrhosis or advanced fibrosis showed a reduction in the incidence of hepatic decompensation and the risk of hepatocellular carcinoma after continuous treatment with lamivudine.^{36,40}

Interferon alfa (5 million to 10 million units subcutaneously three times per week, for at least 3 months) used to constitute the main therapy in cases of HBV, achieving a successful response in approximately 30% of cases. However, its multiple side effects (fever, myalgias, bone marrow suppression, and depression, among others) made it difficult to tolerate. Furthermore, the potential for overt liver failure made it a risky treatment in people with advanced liver disease. Lamivudine is an orally effective antiviral agent that competitively inhibits the viral DNA polymerase. Its administration is associated with a more rapid seroconversion to HBeAg-positive status, a more rapid loss of HBeAg, improved aminotransferase levels, and a 3- to 4-log reduction in circulating levels of HBV DNA in the first 3 months of therapy. It is also associated with improved liver histologic findings in cases of chronic hepatitis. Lamivudine tends to be tolerated

well. Its major limitation is development of drug resistance. Adefovir is an orally effective nucleotide analogue approved by the U.S. Food and Drug Administration (FDA) for the treatment of HBV infection. It has shown promising results by inhibiting replication of lamivudine-resistant HBV mutants.⁴¹

Entecavir (Baraclude) is an orally administered cyclopentyl guanosine analogue that has been approved for treatment of chronic HBV infection. Large multinational trials have compared entecavir to lamivudine and found superiority for entecavir in terms of HBeAg seroconversion, decrease in serum HBV DNA, normalization of serum ALT, and histologic improvement.⁴² Entecavir has been shown to be effective in lamivudine-resistant patients as well. Telbivudine (Tyzeka) is the unmodified β -L-enantiomer of thymidine. It is approved for patients with chronic HBV and has also been shown to be superior to Lamivudine in suppressing HBV DNA, but other clinical benefit was less obvious.⁴³ Additionally, telbivudine was not effective in patients who developed breakthrough infection while on lamivudine.

Liver transplantation is the treatment of choice in patients with hepatic failure. Recurrence of viral infection in the allograft can be as high as 80% in HBeAg-positive cases where no postoperative prophylaxis is administered. The combination of lamivudine and hepatitis B immune globulin posttransplantation reduced the reinfection rate to approximately 10%, and increased the 5-year HBV-free survival rate to approximately 80%.³⁶ Other posttransplant pharmacologic regimens are now being examined.

HEPATITIS C VIRUS

Molecular Structure

Hepatitis C virus (HCV) is a lipid-enveloped, 9.4-kb, single-stranded RNA virus of the family Flaviviridae, genus Hepacivirus. Six genotypes have been identified, which differ from one another by as much as 30% at the sequence level.⁴⁴ Quasispecies within genotypes demonstrate further genetic heterogeneity and reflect the high rate of mutation seen in viral replication. Over 70% of U.S. cases are due to genotype 1 virus.

Epidemiology/Risk Factors for Transmission

There are 4 million people infected with HCV in the United States, or approximately 1% of the population. Additionally, there are 170 million infected worldwide. The most commonly identified factors responsible for infection are exposure to blood or blood products prior to 1992 and intravenous drug use. Other less common risk factors include occupational exposure, nosocomial spread, sexual contacts, tattooing, and vertical transmission, each of which is a relatively inefficient and uncommon means of viral transmission.

Clinical Features

The usual incubation period is 5 to 10 weeks. Most acutely infected patients are asymptomatic and therefore the infection goes unappreciated. Initial laboratory findings after infection include hepatitis characterized by elevated ALT levels (500 to 1,000 IU/mL) and high HCV RNA titers (Fig. 57.11). HCV is thought to be cleared spontaneously in 20% of individuals following primary infection. Hepatitis C infection by itself is almost never associated with acute liver failure. Liver damage in the setting of chronic infection is due to host immune response rather than to viral hepatotoxicity. Ongoing chronic hepatic injury leads to progressive fibrosis and cirrhosis, in

FIGURE 57.11. Clinical course in acute hepatitis C.

most cases undetected until the appearance of overt liver failure decades after the initial infection (Fig. 57.12). The incidence of hepatic decompensation (variceal hemorrhage, ascites, jaundice, encephalopathy) in the setting of cirrhosis is approximately 5% per year. Hepatitis C cirrhosis is strongly associated with the development of hepatocellular carcinoma. Extrahepatic manifestations of hepatitis C include membranoproliferative glomerulonephritis, cryoglobulinemia, diabetes, porphyria cutanea tarda, lichen planus, vitiligo, and non-Hodgkin lymphoma.⁴⁵

The diagnosis of hepatitis C is based on serologic demonstration of HCV RNA and/or antibodies. HCV RNA can be detected weeks earlier than antibodies, which are not observed until approximately 18 weeks after the initial illness.

Treatment

Therapy is indicated in cases of chronic hepatitis C with elevated serum aminotransferase concentrations and chronic hepatitis on liver biopsy. The current treatment of chronic hepatitis C is via a combination of pegylated interferon alfa and ribavirin. Pegylation of interferon alfa optimizes its pharmacodynamics and pharmacokinetics by providing sustained concentrations after single weekly injections. Its principal mechanism of action seems to be the immune clearance of infected cells, perhaps via mobilization of endogenous

FIGURE 57.12. Clinical course in chronic hepatitis C.

microRNAs that participate in interference with HCV replication.⁴⁶ Ribavirin is a synthetic guanosine analogue that prevents relapses during and after therapy in patients who exhibit an initial response. Approximately 80% of patients with genotype 2 or 3 infection and 50% of patients with genotype 1 infection show sustained virologic response with therapy. Male sex, race, advanced age, chronic infection, fibrosis, and high body mass index are associated with diminished rates of sustained virologic response. Transplantation is the treatment of choice in terminal cases of hepatitis C where hepatic recovery is not expected and HCV cirrhosis has become the most common indication for orthotopic liver transplantation (OLT). Transplantation ameliorates the sequelae of portal hypertension and cancer risk associated with a cirrhotic liver, but viral reinfection after OLT is immediate and universal. Furthermore, HCV disease progression to graft cirrhosis is accelerated after transplant as opposed to the rate seen in native livers.⁴⁷

HEPATITIS D VIRUS

Molecular Structure

The hepatitis D virus (HDV), or delta agent, is an incomplete RNA virus that requires the concomitant presence of HBV for viral assembly and propagation. The only enzymatic activity of HDV is a ribozyme that autocleaves the circular RNA and makes it linear. The HDV genome is a 1,680-nucleotide, single-stranded circular RNA.⁴⁸ Eight genotypes have been proposed.⁴⁹ A single HDV antigen is encoded, it is a structural component of the virion, and a lipoprotein envelope is provided by HBV.

Epidemiology/Risk Factors for Transmission

It is estimated that HDV is found in approximately 5% of HBV carriers. Due to its dependence on HBV, HDV always occurs in association with HBV infection. Transmission is similar to that of HBV, via parenteral or sexual exposure to blood or body fluids. HDV hepatitis occurs only in HBsAg-positive patients.

FIGURE 57.13. Synchronous infection with hepatitis B virus and hepatitis D virus.

FIGURE 57.14. Superinfection of chronic hepatitis B carrier with hepatitis D.

Clinical Features

Acute infection is diagnosed by the presence of anti-HDV IgM. Anti-HBc IgM distinguishes coinfection from superinfection (Figs. 57.13 and 57.14). The diagnosis in patients with chronic liver disease is made by the presence of HBsAg and antibodies against HDV in the serum and confirmed by the presence of HDV antigen in the liver or HDV RNA in the serum (Fig. 57.15). Acute liver failure is seen with both coinfection (HDV and HBV simultaneously infect the host) and superinfection (HDV infects a host already infected with HBV). Superinfection seems to be associated with a higher mortality rate. Chronic HDV and HBV infection may coexist. Cirrhosis is observed in at least two thirds of patients and occurs at a younger age than in patients infected with HBV alone.^{50,51}

Treatment

Treatment and prevention of HDV are associated with that of hepatitis B, with which it always coexists. Vaccination with the hepatitis B vaccine is contributing to the decline in the incidence of HDV. α -Interferon (IFN) is the only currently

FIGURE 57.15. Clinical course of chronic hepatitis D infection.

available treatment for chronic HDV. Response rates correlate directly with dosage, and relapses are frequent after dose reduction. Sustained responses associated with clearance of HBsAg, improvement of liver histologic appearance, and conversion to HBsAb are unusual and relapses common. Treatment is complicated by the side effects of IFN, which include depression, weight loss, myalgias, fatigue, flulike symptoms, and liver decompensation, among others. Pegylated IFN could be a potentially useful long-term therapy. IFN in combination with ribavirin for chronic cases has not been found to be superior to IFN monotherapy. Liver transplantation is the only option in cases of end-stage liver disease. Allograft reinfection rates with long-term administration of hyperimmune serum against HBsAg seem to be lower for HDV than for HBV.^{50,51} Several studies have shown that patients transplanted for HDV-related disease have better outcomes than those who undergo OLT for HBV alone.⁵² The presence of HDV appears to be protective, possibly via suppression of HBV replication. HDV may inhibit HCV replication as well and mitigate HCV recurrence after OLT in a similar fashion.

HEPATITIS E VIRUS

Molecular Structure

Hepatitis E virus (HEV) is a nonenveloped single-stranded RNA virus. It is 30 nm in diameter and is most similar to other viruses of the Caliciviridae family. There are three large open reading frames, the first of which is 1,693 codons and codes for nonstructural proteins. The second is 660 codons and encodes structural proteins. The third is smaller and of undetermined function. There are thought to be four genotypes.⁵³

Epidemiology/Risk Factors for Transmission

Hepatitis E is enterically transmitted (*waterborne hepatitis* or *enterically transmitted non-A, non-B hepatitis*) and is epidemiologically similar to HAV. Infection has been prominently observed in Asia, Africa, the Middle East, and Central America. In addition, vertical transmission from mother to child has been documented and can be a source of perinatal morbidity and mortality.

FIGURE 57.16. Clinical course of chronic hepatitis E infection. (Reproduced with permission from Expert Reviews in Molecular Medicine: (99)00129—5 h.htm; 6 December 1999.)

Clinical Features

HEV generally causes a self-limited acute infection, although chronic infection has been described in organ transplant recipients. The incubation period usually lasts 3 to 8 weeks, and most individuals recover without chronic findings after a transient cholestatic jaundice (Fig. 57.16). However, young adults and women in late stages of pregnancy may develop fulminant cases of hepatitis E. Mortality from HEV is 0.5% to 4% in the general population but up to 20% in pregnant women.⁵⁴⁻⁵⁶ Diagnosis is aided by amplification of serum and fecal viral genomes during the acute phase. The presence of anti-HEV IgM or follow-up demonstration of IgG may be required.

Treatment

There is currently no specific treatment for HEV infection, although vaccines against HEV are in development and appear to be highly effective. Improving sanitation and purifying or boiling water can reduce the incidence of this disease.

CYTOMEGALOVIRUS

Cytomegalovirus (CMV) is a member of the β -Herpesviridae family. It is usually associated with mild hepatitis but may occasionally cause acute liver failure. Transmission can be intrauterine; perinatal or postnatal; through intimate contact of infected fluids such as blood, saliva, or urine; or through transplanted organs. Infection is lifelong due to latency of the virus and can be detected in up to 70% of individuals in U.S. urban cities. Organ injury can occur as a result of primary infection or reactivation of a latent infection. In the neonatal period, severe cases of congenital infection are usually generalized and can be fatal. In immunocompetent adults, liver dysfunction tends to be found in association with CMV mononucleosis. In immunosuppressed adults, infection leads to liver dysfunction with jaundice and at times liver failure. Acalculous gangrenous cholecystitis may also be encountered.^{32,57,58}

Shell vial assay is a more sensitive and rapid method than conventional human fibroblast culture of saliva, urine, bronchoalveolar lavage fluid, or blood to detect infection. Currently, the use of CMV antigenemia assays and detection of CMV by PCR amplification from serum has greatly increased the rapidity and ease of diagnosis. Detection of IgM is helpful

only in neonatal infection; serology is not useful as a diagnostic tool in adults. Liver biopsy is of importance to establish the diagnosis of hepatitis. Microscopic examination shows inflammation and injury ranging from fatty changes to necrosis to fibrosis. Giant multinucleated cells and large nuclear inclusions can be encountered in hepatocytes and bile duct epithelial cells.^{32,57,58}

Several drugs are available for the systemic treatment of CMV, including ganciclovir, valganciclovir, foscarnet, and cidofovir; anti-CMV hyper-immune globulin is sometimes used as an adjunctive therapeutic modality.⁴¹

EPSTEIN-BARR VIRUS

Epstein-Barr virus (EBV) is a DNA virus and member of the Herpesviridae family. Infection persists for life due to latency of the virus, and is usually transmitted in the course of close personal or intimate contact via oral secretions. Some degree of liver involvement is encountered in almost all cases of EBV mononucleosis. It is usually mild, with no major clinical manifestations, and resolves spontaneously. The presence of jaundice may reflect either more severe hepatitis or an associated hemolytic anemia. Occasional cases of fatal acute liver failure have been reported in both immunocompromised and immunocompetent patients. Leukocytosis is usually present, with lymphocytosis and monocytois. The monospot test is sensitive but not specific. Diagnosis is by detection of nucleic acids with in situ hybridization, Southern blot analysis, and PCR of involved organ biopsies. Detection of IgG and IgM antibodies improves sensitivity and specificity. No antiviral agent has so far proved effective in EBV hepatitis. Liver transplantation has been reported in life-threatening situations.^{41,57,59,60}

HERPES SIMPLEX VIRUS

The prevalence of antibodies to herpes simplex virus 1 (HSV-1) in the populations of industrialized nations is 80% in lower socioeconomic strata (SES) and 50% in higher SES; prevalence of antibodies to herpes simplex virus 2 (HSV-2) is approximately 20%. Fulminant hepatitis is a rare complication of HSV infection, but those at risk include neonates and immunocompromised, malnourished, and pregnant adults. Fulminant hepatitis is usually associated with multiorgan involvement and carries a high (>80%) mortality rate. Clinical features include fever, anorexia with nausea, abdominal pain, leucopenia, and coagulopathy. Liver biopsy is of prime importance to establish the diagnosis, especially in pregnant women. Microscopic examination shows diffuse eosinophilic intranuclear inclusion bodies, multinucleated cells, widespread necrosis, and slight inflammation. Cowdry A-type intranuclear inclusions are typical. Confirmation is by means of HSV DNA detection by PCR. Approved antivirals include acyclovir, famciclovir, and valacyclovir. Treatment with intravenous acyclovir should be started prior to confirmation of the etiology, given that progression of the disease is extremely rapid and lethal. Liver transplantation can be considered even in selected cases of disseminated disease.^{41,57,58}

VARICELLA ZOSTER VIRUS

Herpesvirus varicellae (also called varicella zoster virus [VZV]) is usually associated with mild hepatitis but may occasionally cause acute liver failure. Up to one fourth of children with varicella (chickenpox) may exhibit temporary mild biochemical liver abnormalities. Reye syndrome may be encountered during the convalescence period, especially in those who receive aspirin. In such cases, mortality can be as high as 30%. Fulminant fatal hepatic failure is uncommon, but generally

affects immunocompromised patients. Confirmation of the diagnosis can be achieved by isolation of the virus from involved tissues. Varicella zoster immune globulin therapy should be considered after exposure to the virus by immunocompromised or pregnant patients who lack immunity to VZV. Current therapies for VZV infection in immunocompetent and immunocompromised hosts include acyclovir, valacyclovir, and famciclovir. CDC guidelines should be followed for infection control.^{32,41,57}

ACUTE LIVER FAILURE

Definition

6 Acute liver failure (ALF) is an uncommon but serious condition, with approximately 2,000 to 2,300 cases per year in the United States,⁶¹ which carries a high mortality rate of 60% to 80%.⁶² It is characterized by rapid deterioration of liver function as well as coexistence of hepatic encephalopathy in a previously healthy individual without a known hepatopathy. Currently, emergency liver transplantation is the only therapeutic option available, and the King's College Criteria are widely accepted as the standard of guidance. ALF is responsible for about 6% of all liver-related deaths, and approximately 6% of adult liver transplant recipients undergo transplantation with this indication.⁶³

The most widely accepted definition includes an international normalized ratio (INR) greater than or equal to 1.5 and any degree of mental alteration (encephalopathy) in a patient without preexisting cirrhosis and with an illness of less than 26 weeks' duration.⁶⁴ Patients with Wilson disease, vertically acquired hepatitis B, or autoimmune hepatitis can be considered to have ALF if the disease process has started within 26 weeks. Although the literature suggests hyperacute (<7 days) and subacute (>21 days but <26 weeks) forms, they do not have prognostic significance except with hyperacute failure, which may carry a better prognosis since it is mostly due to acetaminophen toxicity.⁶⁶

Diagnosis

A high index of suspicion is vital in early recognition of the disease process. Patients with evidence of moderate to severe degrees of hepatitis and any degree of encephalopathy with or without coexistence of coagulopathy as evidenced by an INR greater than or equal to 1.5 require hospitalization, since that process may progress to death rapidly.⁶⁵ Likewise, early transfer to an intensive care unit (ICU) setting in a liver transplant center is important (especially before approaching grade III or IV encephalopathy), since worsening encephalopathy can potentially hamper transportation efforts because of concern over increased intracranial pressure.

Detailed history taking from accompanying persons, including medications/herbal supplements taken and recent social history, is essential. Stigmata of chronic liver disease need to be assayed during the physical examination, although jaundice might be a late manifestation of the disease process. The initial laboratory testing shown in Table 57.2 is recommended.⁶⁵

Transjugular liver biopsy can be considered as part of the initial workup to rule out neoplastic infiltration or HSV/herpes zoster virus (HZV) hepatitis,⁶⁶ although its routine application is still considered controversial.

Etiology

It is important to elicit the etiology of ALF in an effort to administer the appropriate antidotes and to better anticipate

TABLE 57.2**MANAGEMENT IN ACUTE LIVER FAILURE: INITIAL LABORATORY EVALUATIONS**

Serum chemistries
Sodium, potassium, chloride, bicarbonate, calcium, magnesium, phosphate, glucose, BUN, creatinine, amylase, lipase
Hepatic panel
AST, ALT, alkaline phosphatase, total bilirubin, albumin
Prothrombin time/INR
Complete blood count
Arterial blood gas, lactate, ammonia
Toxicology screen
Viral hepatitis serologies
Anti-HAV IgM, Hep B surface Ag, Anti-HBV core IgM, anti-HCV, anti-HEV IgM (if indicated)
Anti-VZV IgM, Anti-HSV IgM
Autoimmune markers
ANA, ASMA, IgG levels, SPEP
Pregnancy test
Serum ceruloplasmin level and 24-h urine copper collection (if Wilson disease is suspected)
Ag, antigen; ALT, alanine aminotransferase; ANA, antinuclear antibody; ASMA, anti-smooth muscle antibody; AST, aspartate aminotransferase; BUN, blood urea nitrogen; HAV, hepatitis A virus; HBV, hepatitis B virus; HCV, hepatitis C virus; HEV, hepatitis E virus; HSV, herpes simplex virus; IgM, immunoglobulin M; INR, international normalized ratio; SPEP, serum protein electrophoresis; VZV, varicella zoster virus.

prognosis and hence the need for liver transplantation.⁶⁷ Etiology seems to have some geographic variances. In the United States, the etiology is reported to be acetaminophen overdose in 46% of cases, followed by indeterminate causes (14%), drug related (11%), HBV (7%), autoimmune hepatitis (5%), and Wilson disease (2%).⁶⁸ In the United Kingdom, acetaminophen toxicity is reported to be as high as 60.9%,⁶⁹ whereas in France, the reported etiologies are viral infection with hepatitis A and B (31%), acetaminophen toxicity (20%), other drug overdose (18%), and unknown (17%).⁶⁶

Viral Hepatitis. In those with HAV, ALF occurs in up to 0.4% of cases; age over 40 years and preexisting liver disease represent a higher risk. In those with HBV, ALF occurs in up to 1.2% of cases. ALF may occur due to acute hepatitis or reactivation of a chronic carrier state. HDV coinfection and HEV should be suspected in endemic areas. VZV, HSV, and CMV are other rare viral causes.⁶⁷

Drug-induced Liver Injury. Intrinsic hepatotoxins are usually dose dependent, while idiosyncratic responses are unpredictable and are not dose dependent. Acetaminophen is a good example of the dose-dependent form, generally greater than 10 g/d but sometimes reported to be as low as in the 3 to 4 g/d range. Glutathione becomes depleted with excess free NAPQI (a toxic byproduct of acetaminophen) reacting with hepatocytes, causing the liver injury.⁶⁷ In the presence of poor nutritional state or alcoholism, glutathione levels are chronically depleted, further contributing to acetaminophen toxicity. Stevens-Johnson syndrome, caused by phenytoin, amoxicillin-clavulanate, carbamazepine, and halothane, is a form of hypersensitivity

idiosyncratic reaction, while isoniazid, valproate, and amiodarone mainly cause metabolic idiosyncratic reactions.

Other. Acute Budd-Chiari syndrome, veno-occlusive disease due to medications and herbs, and malignancies involving the liver (i.e., lymphoma, angiosarcoma) are less common causes of ALF.⁶⁵ Acute fatty liver of pregnancy (AFLP) and HELLP (hemolysis, elevated liver enzymes, low platelets) are important diagnoses to be considered among pregnant women presenting with manifestations of ALF. AFLP occurs during the third trimester due to deficiencies in long-chain 3-hydroxyacyl-CoA dehydrogenase in both the mother and the fetus with rapid deposition of triglycerides and free fatty acids into hepatocytes. HELLP also occurs during the third trimester or immediately postpartum. Autoimmune hepatitis (AIH) can present acutely with absence of autoimmune markers, where the diagnosis is made by exclusion and transjugular liver biopsy. In the fulminant form of Wilson disease, chelator treatment is ineffective and diagnosis is usually based on familial history of liver disease in a young adult with Coombs-negative hemolysis and low serum alkaline phosphatase or uric acid levels. Kayser-Fleischer rings are present in 50% of patients.⁶⁴ Diagnosis is usually confirmed by hepatic copper content greater than 250 $\mu\text{g/g}$ in patients homozygous for Wilson disease, and the rate of urinary excretion may exceed 100 $\mu\text{g}/24 \text{ h}$.⁷⁰ Heat stroke, mushroom ingestion, EBV, and parvovirus B19 may be considered as rare causes of ALF.⁶⁶

Clinical Features, Management, and Treatment

Acute liver injury in the absence of hepatic encephalopathy is a reversible entity, unless an underlying chronic liver disease is present. Altered mental status accompanied by jaundice and elevated serum aminotransferases and prothrombin time (PT)/INR is the hallmark of the presentation. Rapid loss of liver mass can lead to multiorgan system failure and eventual death.⁶⁵ Liver transplantation needs to be considered and accomplished prior to reaching this moribund state. Therefore, early transfer to a liver transplant center ICU setting has paramount importance due to this time-limited window of opportunity for high-acuity ALF patients.⁷¹ Encephalopathy may be accompanied by myopathy and neuropathy, loss of vascular tone with hypotension, cardiac dysfunction, acute lung injury, gastrointestinal bleeding, pancreatitis, acute renal failure, and/or disseminated intravascular coagulation and cholestasis.⁷¹ Intracranial hypertension is recognized in 50% to 70% of patients in stage 4 coma. Therefore, neurocritical care, with ability to rapidly respond to hemodynamic changes, becomes an important issue in management. Other precepts are maintenance of normoxia, euglycemia, control of seizures, therapeutic hypothermia, osmotic therapy, and judicious hyperventilation.⁷¹

Initial management includes identification and treatment of infection, titration of intravascular volume expansion, and selection of fluids to minimize cerebral edema. Hypertonic saline may be considered to maintain serum sodium in the mildly hypernatremic range. Norepinephrine is the vasopressor of choice and early initiation of renal replacement therapy is important for tight control of intravascular volume. Mild reduction in blood CO_2 tension can also restore cerebral vasoreactivity and autoregulation.⁷¹

Advanced cerebral edema is associated with hyperventilation, hypertension, papillary abnormalities, decerebrate posturing, and ultimately uncal herniation and death. Arterial ammonia levels greater than 200 $\mu\text{g/dL}$ may be correlated with herniation.⁶⁵ Although well-powered controlled trials

are still needed to determine the role of intracranial pressure monitoring,⁷² management should aim to keep the cerebral perfusion pressure (mean arterial pressure – intracranial pressure) over 50 mm Hg and the intracranial pressure below 25 mm Hg. Sustained pressures greater than these values for longer than 2 hours usually signifies irreversible brain damage.⁶⁵ Mannitol intravenous bolus doses of 0.5 to 1 g/kg are effective in decreasing cerebral edema by maintaining osmotic diuresis and can be repeated provided serum osmolality does not exceed 320 mosm/L.⁶⁴ Profound coagulopathy (INR >7) and/or planned invasive procedures warrant correction of coagulopathy with fresh frozen plasma (FFP) in combination with recombinant activated factor VII (rFVIIa).⁶⁴

Liver Transplantation

Establishing the cause of ALF is an important determinant of outcomes following liver transplantation, with the best results achieved for Wilson disease and the worst seen with idiosyncratic drug reactions. Overall, survival rates following transplantation at 1 year are 7% to 15% below those obtained for elective transplants in patients with chronic liver disease but are similar to survival of chronic liver disease patients going to liver transplantation from an ICU setting.⁷³

Patients who are at high risk of death should be identified early in the course of ALF and listed and transplanted in a timely fashion. Therefore, it is also crucial to identify patients who are too sick to benefit from liver transplantation. Relative contraindications for liver transplantation can be summarized as (a) sustained cerebral hypoperfusion detected as cerebral perfusion pressure less than 40 mm Hg for longer than 2 hours, (b) arterial vasodilatation requiring more than 1 µg/kg per minute norepinephrine infusion, and (c) acute respiratory distress syndrome requiring fraction of inspired oxygen (FiO₂) at 60% and positive end-expiratory pressure (PEEP) at greater than 12 cm H₂O.⁷¹

TABLE 57.3

STAGING

KING'S COLLEGE CRITERIA OF POOR PROGNOSTIC INDICATORS

Acetaminophen-induced ALF:

Arterial pH <7.3 irrespective of coma grade

OR all of the following:

INR >6.5, creatinine >3.4 mg/dL (300 µmol/L), grade III/IV encephalopathy

Non-acetaminophen-induced ALF:

INR >6.5

OR any three of the following:

Age <10 or >40, drug toxicity or undetermined etiology, jaundice >7 days before encephalopathy, INR >3.5, bilirubin >17 mg/dL (300 µmol/L)

ALF, acute liver failure; INR, international normalized ratio.

Liver Support Systems

Various biologic and charcoal-based sorbent systems have been tested to date with no demonstrable clinical impact. Total plasma exchange has been studied retrospectively, in an attempt to stabilize the ALF patient until a liver graft is identified or self-regeneration occurs.⁶³ Sorbent systems have shown transient detoxification with no long-term benefit at the expense of worsening coagulopathy. Porcine cell-based and hepatoblastoma-derived extracorporeal systems, the Molecular Adsorbents Recirculating System (MARS),⁷⁴ and the Prometheus System⁷⁵ are available only for clinical trials and their future in the management of acute liver failure currently remains unclear.⁶⁴

Meets Definition	<ul style="list-style-type: none"> • rapid deterioration of liver function tests with encephalopathy • no previous liver disease (liver bx may help)
Etiology	<ul style="list-style-type: none"> • acetaminophen tox most common, then acute viral Hep (B and A, not C) • Less Common: drug reaction, Autoimmune Hepatitis, Wilson's
Management	<ul style="list-style-type: none"> • Early transfer to Liver Transplant Center • Treat infection, restrict IIV, ICP monitoring controversial • Ultimately must decide: continue observation vs OLT
Outcomes	<ul style="list-style-type: none"> • 25-50% survival without OLT (depends on etiology/severity) • 60-75% survival with OLT: lower outcomes than with other indications

ALGORITHM 57.2

ALGORITHM 57.2.

Prognosis

Accurate prognosis in ALF is important to avoid unnecessary liver transplantation, and the traditionally accepted King's College Criteria are most commonly used for this purpose (Table 57.3). Of note is that the Model for End-Stage Liver Disease (MELD) system cannot be applied in ALF.⁶⁴

ALF due to acetaminophen overdose, hepatitis A, shock liver, or pregnancy-related disease showed a 50% or more transplant-free survival, while most other etiologies have shown less than 25% transplant-free survival.⁶⁴ Other proposed but not widely accepted poor prognostic criteria have been α -fetoprotein levels, ratio of factor VIII and V, liver histology, and serum phosphate levels.

Recipients who underwent liver transplantation for drug-induced ALF in the United States from 1987 to 2006 were retrospectively studied, and the most common drug groups were identified as acetaminophen, antituberculosis medications, antiepileptics, and other nontuberculosis antibiotics. Patients age 7 years or younger with antiepileptic toxicity had the highest risk of death following liver transplantation compared to all other groups. Being on life support and elevated serum creatinine were identified as other predictors of poor survival after liver transplantation.⁷⁶

CHAPTER 58 ■ CIRRHOSIS AND PORTAL HYPERTENSION

MICHAEL R. MARVIN AND JEAN C. EMOND

KEY POINTS

- 1 Although the causes of cirrhosis and the morphologic and histologic changes seen in the liver overlap significantly, oxidative stress leading to chronic injury and inflammation appears to be a common theme.
- 2 The key mediator in alcohol-induced liver disease is acetaldehyde, which produces numerous deleterious effects on the liver.
- 3 Nonalcoholic fatty liver disease or nonalcoholic steatohepatitis (NASH) is characterized by infiltration of the liver with fat and is associated with obesity, hyperlipidemia, and non-insulin-dependent diabetes.
- 4 Viral hepatitis is the most common cause of cirrhosis worldwide, accounting for at least 50% of cases.
- 5 Budd-Chiari syndrome is a rare disease caused by mechanical obstruction of the hepatic veins owing to obstructing webs or membranes (most commonly in Asia and Africa) or thrombosis secondary to hypercoagulable states and neoplasms (most commonly in the West).
- 6 Hepatorenal syndrome is a complication of cirrhosis, usually associated with ascites, characterized by progressive renal failure in the absence of intrinsic renal disease.
- 7 Hepatic encephalopathy is a neuropsychiatric syndrome that occurs in the setting of hepatic disease and is characterized by variable alterations in mental status ranging from deficits detectable only by detailed psychometric tests to confusion, lethargy, and ultimately coma.
- 8 Portal hypertension is defined as a portal pressure above the normal range of 5 to 8 mm Hg and can be secondary to cirrhosis (hepatic), portal vein thrombosis (presinusoidal), or hepatic venous obstruction (postsinusoidal).
- 9 The Child-Turcotte-Pugh score is a scoring scale that incorporates clinical and laboratory data as a means to assess the functional status of the liver, estimate hepatic reserve, and predict morbidity and mortality of liver disease. The Model for End-stage Liver Disease (MELD) score is a highly reliable prognostic marker for cirrhosis, is calculated from standard laboratory tests, and has replaced the Child-Turcotte-Pugh score in liver transplant candidate stratification.
- 10 The use of the transjugular intrahepatic portosystemic shunt (TIPS) has become first-line therapy for refractory or recurrent bleeding esophageal varices, with 6-month and 1-year patency rates and prevention of rebleeding in 92% and 82% of patients, respectively.
- 11 Although the surgical interventions for treatment of bleeding varices are divided into three main types—liver transplantation, shunt procedures, and devascularization procedures—the only definitive procedure in patients with cirrhosis is orthotopic liver transplant.
- 12 Spontaneous bacterial peritonitis is a potentially lethal complication of unknown etiology associated with portal hypertension with ascites that occurs in up to 10% of patients.

CIRRHOSIS

Background and Definition

Cirrhosis is the end result of multiple, varied, repeated or chronic pathologic insults to the liver with subsequent repair that cause a derangement in the hepatic architecture; the primary histologic features are marked fibrosis, destruction of vascular and biliary elements, regeneration, and nodule formation (Fig. 58.1). In addition to progressive failure of hepatic function, portal hypertension is the most prominent clinical manifestation associated with cirrhosis, but it is possible to have portal hypertension in the absence of cirrhosis. The continuum of cirrhosis to liver cancer and its devastating clinical consequences requires us to consider hepatocellular carcinoma as a central complication of cirrhosis.

Pathophysiology

Cirrhosis is caused by a wide range of pathologic entities, including the viral hepatitis, alcohol, metabolic disorders, drug toxicity, and biliary obstruction, among others (Table 58.1). Triggered by the underlying cause, the liver is exposed to a broad range of pathologic injuries leading to hepatocyte death and

the gradual loss of architectural integrity made permanent by the development of fibrosis. The capacity of the liver to regenerate is a distinct feature of the liver metaphorically represented in the Promethean myth, and the liver is able to absorb injury without structural alteration. However, the capacity of the liver to regenerate is finite, and understanding the deviation from successful regeneration with restoration of hepatocyte mass and normal architecture to the path leading to fibrogenesis and cirrhosis remains a central question in liver biology.¹ Significant progress in our understanding of the evolution of liver fibrosis, which ends with cirrhosis, has been gained in recent years.

- 1 The pathway from the injuring agent to fibrosis is of growing interest, and the central role of oxidative stress in many forms of liver injury has received growing attention. Alcoholic liver disease has long been known to be associated with consequences of oxidative stress in the liver with failure of homeostatic mechanisms.² Obesity and metabolic syndrome, a major health problem in the United States, may produce hepatic injury and may potentiate the effects of viral injury.^{3,4} In addition to direct oxidative stress, hepatocyte injury is mediated by a variety of mechanisms including proinflammatory cytokines¹ and failure of reparative or modulatory pathways.⁵

The failure of protective or reparatory mechanisms is also widely studied.⁶ Over time, fibrosis is the inexorable consequence

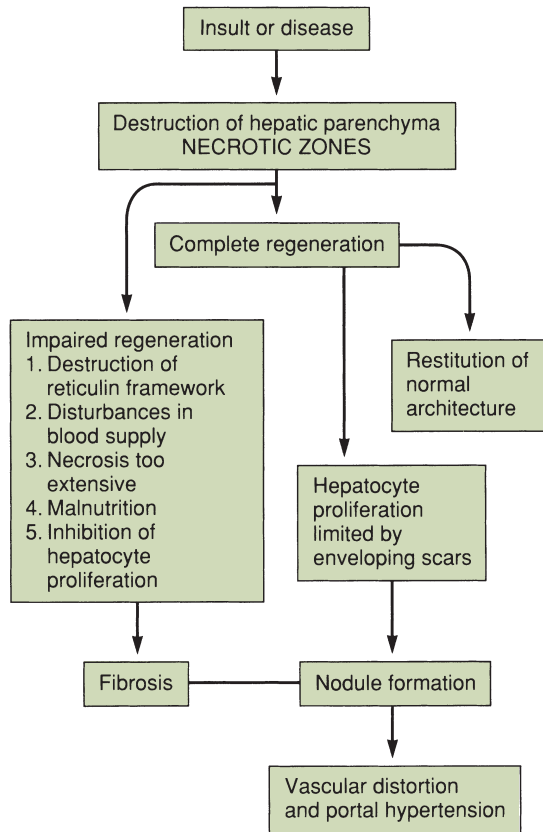

FIGURE 58.1. Evolution of cirrhosis. Fibrosis develops in nonregenerative necrotic areas, producing scars. The pattern of nodularity and scars reflects the type of response to injury (e.g., uniform vs. nonuniform necrosis) and the extent of injury.

Idiopathic

of injury and the primary cell implicated in the formation of fibrosis is the hepatocyte stellate cell (HSC), located in the perisinusoidal space of Disse (Fig. 58.2).⁷ In the normal liver, these cells are quiescent and are primarily responsible for the storage of vitamin A.⁸ Injured hepatocytes release soluble factors that activate HSCs, as evidenced by cellular enlargement and proliferation, an increase in rough endoplasmic reticulum,

FIGURE 58.2. Matrix and cellular alterations in hepatic fibrosis. **A:** In normal liver, a modest amount of low-density matrix is present in the subendothelial space of Disse. **B:** In the fibrotic liver, the accumulation of fibril-forming matrix in this region leads to “capillarization” of the sinusoid and functional changes in all neighboring cell types. (From Friedman SL, Arthur MJP, Millward-Sadler GH. Cirrhosis and hepatic fibrosis. In: Wright R, et al., eds. *Liver and Biliary Disease*, 3rd ed. London: Bailliere Tindall, 1992: 822–881, with permission.)

loss of vitamin A droplets, expression of actin filaments, and increased expression of “fibril-forming” collagen types I, III, and V.⁹ They also express components of the extracellular matrix, including heparan sulfate, dermatan, chondroitin sulfate,¹⁰ laminin,¹¹ and fibronectin.¹² Macrophages within the liver (Kupffer cells) secrete transforming growth factor- β 1 (TGF- β 1), which appears to be critical for the activation of HSCs.^{13,14} Both TGF- β and platelet-derived growth factor (PDGF) have been shown to enhance proliferation and fibrogenesis in animal models,^{14–16} with TGF- β being the primary stimulator of collagen synthesis and fibrosis. Further evidence implicating TGF- β in the production of hepatic fibrosis is the observation that levels of TGF- β are reduced by therapy with interferon- α in patients who are positive for hepatitis C. This reduction has been correlated with a regression of hepatic fibrosis.¹⁷ As a result of the activation of stellate cells and a subsequent enhancement in collagen and extracellular matrix synthesis, the space of Disse becomes thickened, so that “capillarization” develops and the normal fenestrated architecture of the sinusoidal endothelium is lost.¹⁸ Obliteration of sinusoidal fenestrations may be the essential component of fibrosis-induced hepatocellular dysfunction in cirrhosis, preventing the normal flow of nutrients to hepatocytes and increasing vascular resistance.¹⁹ In addition, production of endothelin-1, a potent vasoconstrictor, by endothelial or stellate cells can cause contraction of the myofilaments within the stellate cell, influencing blood flow to injured areas and contributing to portal hypertension.²⁰ Initially, fibrosis may be reversible if the inciting agents are removed. With sustained injury, the process of fibrosis becomes irreversible and leads to cirrhosis. Growing attention has been given to approaches that might disconnect hepatic injury from the inexorable path of fibrosis.²¹

Classification Systems

Morphology. In 1977, the World Health Organization divided cirrhosis into three categories based on the morphologic characteristics of hepatic nodules (Fig. 58.3).²²

Micronodular Pattern. Nodules are almost always less than 3 mm in diameter, are relatively uniform in size, are regularly

distributed throughout the liver, and rarely contain portal tracts or efferent veins. Micronodular livers are usually of normal size or are mildly enlarged, and the fibrous septa vary in thickness. These changes reflect relatively early disease and are characteristic of a wide range of disease processes, including alcoholism, biliary obstruction, venous outflow obstruction, hemochromatosis, and Indian childhood cirrhosis.

Macronodular Pattern. In this category, nodules vary considerably in size and are larger than 3 mm in diameter, with some nodules measuring several centimeters. Portal structures and efferent veins are present but display architectural distortion. These livers are usually coarsely scarred with variably thick and thin septa and may be either normal or reduced in size. Two separate subcategories are recognized based on the nature of the fibrous septa. In the first one, characteristic of “post-hepatitis” pathology and found in Wilson disease, fine, sometimes incomplete septa link portal tracts; these are difficult to see on gross inspection of the liver. The second is characteristic of “postnecrotic” disease, commonly found in patients with viral hepatitis, and is characterized by coarse, thick septa that are readily apparent on gross examination. Because of the relatively large size of the nodules relative to the size of biopsy specimens, diagnosis by biopsy may be difficult in macronodular cirrhosis.

Mixed Pattern. This description is applied to livers in which both micronodules and macronodules are present in approximately equal proportions.

Etiology. Another commonly used method for classifying cirrhosis is by etiology. The causes of cirrhosis and the morphologic and histologic characteristics of the liver, however, overlap significantly. Oxidative stress leading to chronic injury and inflammation appears to be a common theme of these disorders, which leads to both scar formation and an increased risk of liver cancer.

Alcohol. The relationship between alcohol and liver disease has been well established. In 1849, Rokitsky, referring to the association of alcohol intake and liver disease, coined the term *Laennec cirrhosis*.²³ More than 50% of alcoholics with

FIGURE 58.3. A: Small, shrunken liver and a fairly regular pattern of nodularity. This appearance is rather typical of end-stage cirrhosis, regardless of the cause. B: Photomicrograph of cirrhotic liver tissue, showing irregular nodules of regenerating hepatocytes surrounded by scar. Trichrome stain. (From Stal P, Broome U, Scheynius A, et al. Kupffer cell iron overload induces intercellular adhesion molecule-1 expression on hepatocytes in genetic hemochromatosis. *Hepatology* 1995;21:1308–1316.)

FIGURE 58.4. Alcoholic hepatitis. Mallory bodies (arrows) are evident within the swollen, clear cytoplasm of several hepatocytes. This hyaline material is chemotactic for leukocytes, many of which are seen within the field. Hematoxylin and eosin (H&E) stain $\times 470$.

cirrhosis and two thirds of patients with alcoholic hepatitis and cirrhosis die within 4 years of diagnosis.²⁴ Cirrhosis, however, develops in only 10% to 30% of heavy drinkers.²⁵ The reasons why cirrhosis develops in some alcoholics but not in others are not clear and may depend on a variety of factors, such as genetic predisposition, nutritional effects, concomitant drug use, and viral infection.

Alcoholic liver disease usually begins with a transition of normal architecture to fatty liver and alcoholic hepatitis, indicated histologically by the presence of megamitochondria, Mallory bodies (eosinophilic accumulations of intermediate filaments with cytokeratin proteins), inflammation and necrosis, and ultimately fibrosis (Fig. 58.4). Classically, the morphology of alcoholic cirrhosis is a micronodular pattern.

- 2 Although alcohol may directly activate stellate cells to produce collagen independently of inflammation and necrosis,²⁶ the key mediator in alcohol-induced liver disease is acetaldehyde, the product of alcohol metabolism by the enzyme alcohol dehydrogenase. Acetaldehyde (ADH) produces numerous deleterious effects on the liver, including the following: direct activation of stellate cells²⁷; inhibition of DNA repair²⁸; depletion of glutathione, which impairs mitochondrial function and the ability to handle free radical production; damage to microtubules, which causes protein and water sequestration²⁵; and formation of reduced nicotinamide adenine dinucleotide (NADH), which opposes gluconeogenesis and inhibits fatty acid oxidation, so that steatosis and hyperlipidemia develop.²⁵ ADH is most active in the perivenular/centrilobular zone 3 of the hepatic lobule; as a result, relatively high concentrations of acetaldehyde are found in this area of the liver. In addition, zone 3 is hypoxic because of its distance from portal venous and hepatic arterial inflow. These two factors are presumably responsible for the characteristic initial perivenular location of alcohol-induced liver disease.

Other effects of ADH include induction of lipid peroxidation with subsequent loss of integrity of cell membranes, which causes the characteristic “ballooning degeneration” of alcohol-induced liver disease. Necrosis and inflammation in the perivenular region activate the stellate cells in the space of Disse, so that fibrosis develops. With continued ingestion of alcohol and hepatic injury, expansion of the areas of fibrosis toward the periportal regions leads to bridging fibrosis and ultimately cirrhosis.

Nonalcoholic Fatty Liver Disease/Nonalcoholic Steatohepatitis. As noted earlier, this entity has become a major

- 3 health problem in the United States and adds even further to the litany of health consequences of obesity. Nonalcoholic steatohepatitis (NASH), as this disease was previously called, is only one stage in the nonalcoholic fatty liver disease (NAFLD) process.²⁹ It is characterized by infiltration of the liver with fat, with or without inflammation (hepatitis), that shares pathologic features of alcohol-induced liver injury but occurs in patients who do not abuse alcohol. NAFLD is associated with obesity, hyperlipidemia, and non-insulin-dependent diabetes.³⁰ Most patients who are diagnosed with cryptogenic cirrhosis have NAFLD,³¹ which is the most common cause of abnormal liver test results in the United States.³² In addition to liver injury and cirrhosis, NAFLD is a major risk factor for primary liver cancer (hepatocellular carcinoma [HCC]) and, in addition to hepatitis virus infection, accounts for the rapid rise in the incidence of HCC.³³ More broadly considered, recent reports have identified obesity as a major risk factor for cancer deaths with a 4.5-fold increase of the relative risk for liver cancer in obese subjects.³⁴

- 4 **Hepatitis.** Viral hepatitis is the most common cause of cirrhosis worldwide, accounting for at least 50% of cases. Hepatitis A, B, C, D, and E have all been proved to cause acute hepatitis, characterized histologically by lymphocytic parenchymal and portal inflammation, focal necrosis, ballooning degeneration, cholestasis, Kupffer cell and macrophage hypertrophy and hyperplasia, and lobular disarray. Only hepatitis B, C, and D have been shown to progress to chronic hepatitis, defined by persistent liver cell necrosis and inflammation lasting longer than 6 months. Chronic infection with hepatitis B virus (HBV) develops in fewer than 5% of patients who experience acute HBV infection. The development of cirrhosis in approximately 10% to 20% of chronically infected persons produces an overall rate of cirrhosis of approximately 1%. Hepatitis B remains a major public health problem in Asian countries and Africa, with up to 10% of the population showing evidence of chronic infection. The widespread use of antiviral medications effective against hepatitis B effectively controls progression of the disease in most patients.³⁵ In addition, public health strategies with systematic vaccination of newborns should substantially decrease the incidence of new infections. In contrast, hepatitis C poses a much higher risk of chronic infection, and therapeutic strategies eradicate viral replication in a minority of patients. Of patients with hepatitis C virus (HCV), 90% become chronically infected, and chronic hepatitis develops in 60% of these. Of these patients with chronic hepatitis, 30% progress to cirrhosis,²³ so that the incidence of cirrhosis in patients initially infected with hepatitis C is approximately 10%.

Treatment of HCV hepatitis with interferon- α can completely eradicate infection in a small portion of patients (15% to 30%).³⁶ In patients who respond to interferon therapy, progression to cirrhosis is eliminated and it is generally thought that hepatocellular carcinoma does not develop. In patients who do not respond to interferon therapy, cirrhosis develops in approximately 40%, and hepatocellular carcinoma develops in 16% of these.³⁷ Combination therapy with interferon and ribavirin has improved response rates, producing sustained remissions in 30% to 40% of patients.³⁸ Recently, pegylation of interferon has resulted in new drug formulations that have allowed for once-weekly drug administration and improved sustained response rates to greater than 50%.³⁹ It should be noted that hepatitis C occurs naturally in multiple genotypes, of which types 2 and 3 respond well to treatment with sustained viral suppression in 70% to 80% of patients.³⁹ Most recently, trials of antiviral agents aimed at blocking replication have demonstrated marked reduction of HCV RNA, though the effect is not sustained.⁴⁰

Hepatitis D virus (HDV) is an RNA virus that requires the presence of HBV to be pathogenic. Superinfection of HBV-positive patients with HDV leads to a more rapid clinical

TABLE 58.2

ETIOLOGY

CAUSES OF CHOLESTASIS

Extrahepatic	
Common bile duct stones	Vanishing bile duct syndrome
Cancers	Allograft rejection
Pancreas	Graft versus host disease
Ampulla of Vater	Alagille syndrome
Bile duct	Idiopathic adult ductopenia
Cysts	Primary sclerosing cholangitis
Pancreatic	Hodgkin disease
Choledochal	Cystic fibrosis
Infections	Hepatocellular Cholestasis
Parasites	Genetic
Acquired immunodeficiency syndrome	α -Antitrypsin deficiency
Chronic pancreatitis	Benign recurrent intrahepatic cholestasis
Bile duct strictures	Byler syndrome
Benign	Cholestasis of pregnancy
Ischemic	Abnormal bile acid synthesis
Hodgkin disease	Porphyrias
Biliary atresia	Acquired
Intrahepatic	Viral hepatitis
Primary biliary cirrhosis	Drugs
Space-occupying lesions	Alcoholic hepatitis
Primary or metastatic hepatic tumors	Bacterial infections
Lymphoma	Total parenteral nutrition
Amyloidosis	Renal carcinoma
	Hodgkin disease
	Postoperative cholestasis

course, with progression to cirrhosis in 70% to 80% of patients.⁴¹

Among patients with compensated cirrhosis of viral origin, hepatocellular carcinoma developed in approximately 20% with HCV, 9% with HBV, and 41% with both HBV and HCV.²³ The progressive increase in hepatitis-infected individuals in the United States precedes an epidemic in HCC, which has been well documented and is expected to peak over the coming decade.⁴²

Cholestasis. Cholestasis, defined as a decrease or absence of bile flow into the duodenum, may be caused by intrahepatic or extrahepatic biliary obstruction or defects in the ability of hepatocytes to excrete bile. Causes of cholestasis are presented in Table 58.2. Prolonged biliary obstruction leads to proliferation of bile ducts, formation of bile lakes caused by disruption of bile ducts, fibrosis, and ultimately secondary biliary cirrhosis as a result of the direct toxic effects of bile salts on hepatobiliary elements.

Immune or Inflammatory Cirrhosis. Although cholestasis is a generically toxic insult to the liver that can cause cirrhosis, several diseases that are characterized by cholestasis seem to be caused by underlying immune or inflammatory disorders affecting either small (primary biliary cirrhosis [PBC]) or large (primary sclerosing cholangitis [PSC]) bile ducts. Primary biliary cirrhosis is a chronic, slowly progressive disease that most commonly affects middle-aged women; it is characterized by portal inflammation, destruction of intrahepatic bile ducts, and progression to cirrhosis. Approximately 95% of patients are women, and 95% of these women express antimitochondrial antibodies in serum.⁴³ The autoimmune inflammatory process

damages both the bile ducts and, eventually, the hepatocytes as a result of leakage of bile acids into surrounding parenchyma.⁴⁴ Patients present with fatigue, jaundice, and pruritus, but as many as 50% to 60% of patients may be asymptomatic.⁴⁵ PBC progresses in the majority of patients; median survival times are approximately 10 to 15 years in asymptomatic patients and 7 years in symptomatic patients.^{46,47} Poor prognostic factors include hyperbilirubinemia, advanced age, hepatosplenomegaly, and symptomatic disease. Treatment options include cholestyramine, colchicine, and methotrexate for pruritus and fatigue, and ursodiol for slowing progression of the disease and delaying the need for transplant.^{47,48} Liver transplantation is ultimately required as the definitive treatment in most patients, and the parameters for liver transplantation and its timing are relatively predictable and have been well studied.⁴⁹

Primary sclerosing cholangitis is a chronic, progressive cholestatic liver disease of unknown cause characterized by diffuse segmental intrahepatic or extrahepatic biliary ductular strictures with associated fibrosis and inflammation. The disease has no cure and often leads to secondary biliary cirrhosis, portal hypertension, hepatic failure, and cholangiocarcinoma if hepatic transplantation is not performed. PSC is strongly associated with inflammatory bowel diseases, most commonly ulcerative colitis, and probably shares an underlying disturbance related to disturbed mucosal immunity of the gastrointestinal tract.⁵⁰ Approximately 70% of patients with PSC also have ulcerative colitis.⁵⁰ Conversely, approximately 5% of patients with ulcerative colitis have PSC, though subtler forms of the disease may be present but clinically asymptomatic. PSC is thought to be autoimmune in nature; elevated levels of autoantibodies and an increased expression of human leukocyte antigen (HLA) class II molecules on biliary epithelial cells

have been observed.^{51,52} Approximately two thirds of patients are male and younger than 45 years of age at the time of diagnosis.^{53,54} Patients with PSC may be completely asymptomatic (up to 50%) or have signs of advanced disease at the time of diagnosis.⁵⁵ Commonly, the diagnosis is made in symptomatic patients after endoscopic retrograde cholangiopancreatography (ERCP) has been performed to evaluate elevated liver enzymes, including alkaline phosphatase and γ -glutamyltransferase. Symptomatic patients have a waxing and waning course and may present with complaints of fatigue (75%), pruritus (25% to 70%), jaundice (30% to 69%), abdominal pain (16% to 37%), and weight loss (10% to 34%).⁵⁰ Complications secondary to progression to cirrhosis are less common and include ascites, variceal bleeding, and acute cholangitis.

The diagnosis of PSC is suggested by a history of inflammatory bowel disease in the setting of elevated liver enzymes and is established by cholangiography. The disease process may range from a single dominant stricture to, more commonly, diffuse multifocal sclerosis of the intrahepatic and extrahepatic bile ducts. Pathologically, bile ductular proliferation, periductal fibrosis and inflammation, ductopenia, and, less commonly, obliterative fibrous cholangitis may be present. PSC may be considered a premalignant condition. Like ulcerative colitis, PSC confers a significant risk of malignant transformation of the biliary mucosa, which is one of the considerations in considering patients for transplantation.⁵⁶ Natural history studies suggest that cholangiocarcinoma occurs in up to one third of patients, although the risk increases with the duration of disease and the degree of cholestasis.⁵⁷ Screening for premalignant changes with ERCP and cytologic examination and serum testing of CA19-9 have been helpful, though both have limited specificity and sensitivity. Recently, it has been proposed that newer analysis methods of biliary material obtained at screening ERCP, including fluorescence in situ hybridization (FISH), may be used for chromosomal abnormalities associated with cancer with an increase in the sensitivity.⁵⁸ Transplantation should be performed before cancer develops and, generally, the discovery of cancer has been considered an absolute contraindication to transplantation because of poor outcomes. Highly selected patients with localized tumors may be transplanted with an acceptable survival rate with intensive preoperative therapy including radiation and chemotherapy, as proposed by Shaw and implemented on a larger scale by the Mayo group.⁵⁹

Metabolic and Genetic Disorders. Some of these diseases are listed in Table 58.1. A description of all the metabolic disorders causing liver disease is beyond the scope of this chapter.

In hemochromatosis of the liver, an inborn error of metabolism causes an increased absorption of iron from the gastrointestinal tract. The pathophysiology of iron-induced hepatotoxicity is related to lipid peroxidation induced by iron in periportal regions of the liver. Activation of stellate cells by cytokines released from Kupffer cells that have phagocytosed necrotic hepatocytes injured by iron toxicity is also contributory.⁶⁰ Over time, the reaction progresses to bridging fibrosis and eventually to a mixed micronodular–macronodular cirrhosis. Treatment includes reduction of iron intake, repeated phlebotomy, and orthotopic liver transplantation.⁶¹

Wilson disease is an autosomal, recessively inherited disease caused by a deficiency in hepatocyte transport of copper into the bile. The disease is characterized biochemically by low serum ceruloplasmin levels and clinically by corneal pigmentation (Kayser-Fleischer rings), neuropsychiatric disease, and hepatic cirrhosis.⁶² As copper accumulates in the liver, periportal inflammation develops that leads to piecemeal and lobular necrosis, bridging fibrosis, and a mixed micronodular–macronodular cirrhosis. Treatment options include chelating agents, such as penicillamine, trientine, zinc salts, and orthotopic liver transplantation.

Venous Outflow Obstruction. Cirrhosis may also result from obstruction of the hepatic veins. Causes include chronic right-sided heart failure as a result of severe tricuspid regurgitation, constrictive pericarditis, and the Budd-Chiari syndrome.

Hepatic dysfunction secondary to passive vascular congestion in the setting of right-sided heart failure and increased right-sided heart pressures is caused by the transmission of increased pressure to the hepatic venous system. This increased pressure leads to sinusoidal congestion, perivenular atrophy, hemorrhagic necrosis, and distortion and enlargement of sinusoidal fenestrations.⁶³ Increased pressure also causes perisinusoidal edema that eventually exceeds the clearance capabilities of hepatic lymphatics, so that ascites develops.⁶⁴ Grossly, the liver is described as having a “nutmeg” appearance in which areas of hemorrhage are interspersed with relatively normal yellowish parenchyma.⁶⁴ Histologically, perivenular fibrosis progresses to bridging fibrosis that spares the portal regions. Portal sparing is characteristic of “cardiac cirrhosis.” In addition to causing ascites, chronic vascular congestion can lead to fibrosis in the space of Disse, which compromises nutrient delivery and contributes to portal hypertension and zone 3 hepatocellular injury.⁶⁵

Budd-Chiari syndrome is a rare disease caused by mechanical obstruction of the hepatic veins (Table 58.3). Obstruction may occur at the level of the terminal hepatic veins, the major hepatic veins, or the vena cava and may be caused by obstructing webs or membranes (most commonly in Africa and Asia) or thrombosis secondary to hypercoagulable states and neoplasms (most commonly in the West).

The range of presentations is wide; some patients are completely asymptomatic, whereas acute hepatic failure or cirrhosis develops in others.⁶⁶ These variations in symptoms are related to the degree and rate of progression of hepatic outflow obstruction. Patients classically present with abdominal pain, hepatomegaly, and ascites. The diagnosis can be made by

duplex Doppler ultrasonography, which has a sensitivity of 85% to 95%.⁶⁷ Computed tomography (CT) and magnetic resonance imaging (MRI) offer optimal characterization of intrahepatic vascular anatomy and are currently used for the planning of complex interventions.⁶⁸

Diagnosis

Although cirrhosis can be asymptomatic for decades, significant information can be obtained by performing a thorough history and physical examination. A history of alcohol abuse, hepatitis, toxin or drug exposure, upper gastrointestinal bleeding, enlarging hemorrhoids, infections, and alteration in mental status suggest the possibility of liver disease. Physical findings associated with cirrhosis are listed in Table 58.4. In addition to these findings, fetor hepaticus, purpura and bruising, decreased body hair, and white nails are common.

Laboratory tests of liver function are indicated if liver disease is suggested by the history and physical examination. Although levels of bilirubin, aspartate aminotransferase, alanine aminotransferase, and alkaline phosphatase are elevated in hepatic disease, the increases are not specific for liver pathology, and levels may be normal even in the setting of significant disease. A very common finding in patients with cirrhosis is thrombocytopenia, caused by hypersplenism and portal hypertension. The platelet growth factor thrombopoietin, which is produced by the liver, has been shown to be decreased in patients with cirrhosis, and this deficit may contribute to the thrombocytopenia associated with hepatic disease.⁶⁹

The definitive diagnosis of cirrhosis usually requires biopsy, either percutaneous or operative, or gross inspection during laparoscopy or laparotomy. Noninvasive methods to diagnose cirrhosis include ultrasonography, CT, and MRI, which generally reveal an atrophic, nodular liver and an enlarged spleen. More recent work suggests that subtle changes in the hepatic veins may be early markers of cirrhosis.⁶⁸ Ultrasonographic criteria for cirrhosis include the demonstration of multiple nodular irregularities on the ventral liver surface that are clearly separate from the anterior abdominal wall. Parenchymal texture is altered in the setting of fibrosis, though this feature can be subtle. When these criteria are used, ultrasonography has been shown to have a sensitivity, specificity, and accuracy of approximately 90% in the diagnosis of cirrhosis.⁷⁰ Indirect evidence of cirrhosis includes endoscopically discovered varices of the

esophagus, and the presence of splenomegaly detected by CT or MRI.

Manifestations

Renal. Renal complications in cirrhosis are intrinsic to functional dysregulation of vascular tone throughout the body.⁷¹ Several elements come into play and renal dysfunction is characterized by avid sodium retention despite normovolemia or hypervolemia, dilutional hyponatremia secondary to free water overload, ascites, and ultimately renal failure and the hepatorenal syndrome (HRS). The paradoxical arterial vasoconstriction of the renal arterial bed in the face of global fluid overload is critical to the pathophysiology of HRS.⁷² Among the complications of cirrhosis, HRS confers the highest risk of mortality.⁷³ Although HRS is the most dramatic renal complication of liver failure, renal dysfunction in patients with advanced liver disease is generally multifactorial.⁷² Renal insufficiency may develop in a patient with cirrhosis as a direct consequence of the underlying condition (i.e., primary biliary cirrhosis, amyloidosis), as a consequence of excessive diuretic use in the treatment of ascites and fluid overload, or as a secondary reaction to the release of cytokines or hormones by the liver that alter renal function.

Much progress has been made in the understanding of the pathophysiology of HRS focusing on the dysregulation of arterial tone in the end stages of liver disease. Empiric observations that support a functional or “secondary effect” theory include the lack of anatomic renal abnormalities in patients with cirrhosis-related renal dysfunction, the normal function of previously dysfunctional kidneys transplanted into otherwise healthy recipients, and resolution of renal abnormalities after successful hepatic transplantation. Recent clinical studies have defined the critical role of optimizing colloid balance in the patient with cirrhosis⁷⁴ and the exploration of regulators of renal blood flow such as terlipressin in counteracting the deranged vascular tone.⁷⁵

Sodium Retention. Patients with cirrhosis who do not have ascites have relatively normal sodium handling capabilities. Patients in whom ascites develops have a marked inability to excrete sodium. Because of this deficit, sodium intake in excess of renal excretion contributes to fluid overload. Three potential mechanisms have been invoked to explain the cause of sodium retention and the development of ascites in cirrhotic patients. The first is the “underfill” theory, whereby portal hypertension causes an increase in pressure in the splanchnic circulation. Ascites occurs when hepatic lymph production exceeds lymphatic return, with subsequent contraction of the blood volume and renal sodium retention. The second is the “overflow” theory, which suggests that the primary defect is inherent to the kidney. Abnormal renal retention of sodium leads to concomitant water retention, expansion of plasma volume, and subsequently edema and ascites.⁷⁶ The third explanation is the “arterial vasodilation hypothesis,” which suggests that the responsible defect lies within the vascular system, with arterial hypotension as the primary event. Arterial vasodilation in the splanchnic circulation leads to relative peripheral hypovolemia and activation of the renin-angiotensin-aldosterone and sympathetic nervous systems. The effects, in turn, are a release of antidiuretic hormone (arginine vasopressin), enhancement of sodium and water conservation, an increase in effective circulating volume, and edema and ascites.^{77,78} Most evidence supports the latter hypothesis.

The cause of the splanchnic vasodilation is unclear. Some evidence suggests that nitric oxide may be the key mediator. Elevations in portal venous nitric oxide have been reported in both animal and human studies,^{79,80} and inhibitors of nitric oxide production have been shown to reduce the activity of vasoconstrictor systems and enhance renal hemodynamics.⁷⁹

TABLE 58.5

DIAGNOSIS

DIFFERENTIAL DIAGNOSIS OF ACUTE AZOTEMIA IN PATIENTS WITH LIVER DISEASE

	■ PRERENAL AZOTEMIA	■ HEPATORENAL SYNDROME	■ ACUTE RENAL FAILURE
Urinary sodium	<10 mEq/L	<10 mEq/L	>30 mEq/L
Urine/plasma creatinine ratio	>30:1	>30:1	<20:1
Urine osmolality	100 mOsm, or more than plasma osmolality	100 mOsm, or more than plasma osmolality	Equal to plasma osmolality
Urine sediment	Normal	Normal	Casts: cellular debris

The exact role of nitric oxide activity in the pathophysiology of renal disease in cirrhosis remains to be determined.

Water Retention. Patients with cirrhosis and ascites may have a marked inability to handle free water. An increased production of antidiuretic hormone, decreased delivery of fluid to the diluting segments of the nephron, and reduced renal production of prostaglandins all may contribute.⁷⁶ Retention of water leads to dilutional hyponatremia (serum sodium 130 mEq/L), which can cause nausea, vomiting, lethargy, and seizures.⁸¹

6 Hepatorenal Syndrome. Hepatorenal syndrome is a complication of cirrhosis, most often with ascites, characterized by progressive renal failure in the absence of intrinsic renal disease. This syndrome occurs in 10% of hospitalized patients with cirrhosis and ascites.⁸² Manifestations of the disease include progressive oliguria, with urine outputs of 400 to 800 mL/d, a rising serum creatinine level, increased cardiac output, and decreased arterial pressure. The disease process is highly variable and is associated with marked renal cortical vasoconstriction induced by activity of the renin-angiotensin-aldosterone and sympathetic nervous systems. In addition, the powerful endothelium-derived vasoconstrictor endothelin-1, combined with decreased renal production of vasodilator prostaglandins, may play a role.

Hepatorenal syndrome may develop as a result of infection, use of nonsteroidal anti-inflammatory drugs, variceal hemorrhage, or excessive diuretic use in patients who were previously well compensated. The differentiation of hepatorenal syndrome from acute renal failure is possible by the laboratory evaluation of urine and serum samples. Hepatorenal syndrome, however, is virtually indistinguishable by laboratory testing from prerenal azotemia. Both prerenal azotemia and hepatorenal syndrome are characterized by extremely low sodium concentrations in the urine, high urine osmolality, high urine-to-plasma ratios of creatinine, and normal urinary sediment (Table 58.5). Criteria for the diagnosis of hepatorenal syndrome are listed in Table 58.6.

The treatment of ascites in patients with cirrhosis requires sodium and water restriction in addition to the use of diuretics. Excessive use of these treatment modalities may lead to increases in serum creatinine that can be difficult to distinguish from those of hepatorenal syndrome. A failure to respond to cessation of diuretics and fluid challenge suggests hepatorenal syndrome. If liver transplantation cannot be performed, patients with hepatorenal syndrome usually die within months of the development of severe disease, defined as a serum creatinine level above 2 mg/dL.⁷³ Recent studies, however, have shown improvement in renal function in patients with hepatorenal syndrome after treatment with vasopressors and albumin.

Pulmonary. Many pathologic processes in patients with cirrhosis affect pulmonary function. Some reflect an underlying condition that causes both hepatic and pulmonary disease (i.e., cystic fibrosis, α_1 -antitrypsin deficiency); others are primary pulmonary processes, such as interstitial lung disease, primary pulmonary hypertension (portopulmonary hypertension), and obstructive airway disease. Three main pulmonary manifestations of cirrhosis are discussed here; one is related to increased intra-abdominal pressure secondary to ascites, one is caused by intrapulmonary shunting and is known as the hepatopulmonary syndrome, and the last is portopulmonary hypertension.

The presence of copious ascitic fluid can lead to pulmonary dysfunction by compromising diaphragmatic excursion secondary to increases in intra-abdominal and intrapleural pressures. Ascites may also induce large pleural effusions because of the presence of lymphatic transdiaphragmatic communications between the abdomen and thorax.⁸³ Effusions can compress the

TABLE 58.6

DIAGNOSIS

DIAGNOSTIC CRITERIA FOR HEPATORENAL SYNDROME^a

Major Criteria

1. Low glomerular filtration rate, as indicated by serum creatinine >1.5 mg/dL or 24-hour creatinine clearance 40 mL/min
2. Absence of shock, ongoing bacterial infection, fluid losses, and current treatment with nephrotoxic drugs
3. No sustained improvement in renal function (decrease in serum creatinine to \leq 1.5 mg/dL or increase in creatinine clearance to 340 mL/min) following diuretic withdrawal and expansion of plasma volume with 1.5 L of a plasma expander
4. Proteinuria <500 mg/d and no ultrasonographic evidence of obstructive uropathy or parenchymal renal disease

Additional Criteria

1. Urine volume <500 mL/d
2. Urine sodium <10 mEq/L
3. Urine osmolality greater than plasma osmolality
4. Urine red blood cells <50 per high-power field
5. Serum sodium concentration <130 mEq/L

^aAll major criteria must be present for the diagnosis of hepatorenal syndrome. Additional criteria are not necessary for the diagnosis but provide supportive evidence.

From Arroyo V, Ginés P, Gerbes A, et al. Definition and diagnostic criteria of refractory ascites and hepatorenal syndrome in cirrhosis. *Hepatology* 1996;23:164.

pulmonary parenchyma and impair gas exchange, so that ventilation-perfusion mismatch and hypoxemia develop. Patients present with worsening pulmonary symptoms in the setting of increasing abdominal girth. Pulmonary function testing reveals decreases in functional residual capacity and total lung capacity.⁸⁴ Marked improvement in pulmonary function results from large-volume paracentesis.⁸⁵ This intervention decreases the work of breathing and relieves symptoms. With control of ascites, even in the presence of pleural effusions, no other interventions may be necessary.

Hepatopulmonary syndrome occurs in patients with mild to severe hepatic disease and in approximately 10% to 50% of patients with hepatic dysfunction.^{86,87} The criteria for diagnosis include hepatic dysfunction; an oxygen tension below 70 mm Hg or a diffusion gradient above 20 mm Hg, or both; and the presence of pulmonary vascular dilation in patients with structurally normal lungs.⁸⁸ Other manifestations include platypnea (increased shortness of breath with movement from a supine to an erect position) and orthodeoxia (decreased oxygen tension on moving from a supine to an erect position). These two positional deficits in pulmonary function are related to the increased number of dilated capillaries in the basal areas of the lung; flow is increased in these vessels while the subject is standing, so that shunting is increased. Physical findings include clubbing and cyanosis of the nail beds and spider nevi.

Although the underlying cause of hypoxemia in these patients is right-to-left intrapulmonary shunting, ventilation-perfusion mismatch and impaired hypoxic vasoconstriction also play a role. Patients usually present with dyspnea and worsening hypoxemia without evidence of a primary pulmonary process. Initial diagnostic tools include pulse oximetry and arterial blood gas analysis. When significant hypoxemia is found, pulmonary function testing is useful to rule out obstructive or restrictive airway disease. A definitive diagnosis can be obtained by the use of contrast-enhanced echocardiography (bubble study), spiral CT, or angiography, which will confirm the presence of a shunt.⁸⁹ The only effective therapy for this disease is orthotopic liver transplantation.

Portopulmonary hypertension is defined as a mean pulmonary arterial pressure of greater than 25 mm Hg in the setting of liver disease. It is a relatively rare (<10%) complication of cirrhosis that, when severe, carries a substantial risk of mortality and is a relative contraindication to liver transplantation.^{90,91} Screening of patients with cirrhosis by Doppler echocardiography will reveal evidence of elevated right heart pressures, which need to be confirmed by right heart catheterization. Although the high flow state of cirrhosis can elevate right-sided pressures, fixed obstruction of the pulmonary microcirculation is highly lethal and is not likely to improve with liver transplantation. The exact pathophysiology behind portopulmonary hypertension is not known, but portal hypertension is a necessary component of the disease process. The hyperdynamic state in portal hypertension may be the main contributory factor. Treatment with prolonged intravenous infusion of prostaglandins has been shown to be effective in improving pulmonary hemodynamics but does not prolong survival.⁹¹

Hepatic Encephalopathy

7 Etiology. Hepatic encephalopathy is a neuropsychiatric syndrome that occurs in the setting of hepatic disease. It is characterized by variable alterations in mental status, ranging from deficits detectable only by detailed psychometric tests to confusion, lethargy, and ultimately frank coma. The disease may present in association with acute hepatic failure, as a consequence of progression of chronic liver disease, or after the creation of a surgical portosystemic shunt. Usually, a precipitating cause, such as an acute variceal hemorrhage or infection, can be found.

The causative agent in hepatic encephalopathy has been the subject of much debate. Most evidence implicates

ammonia in the development of this condition. Ammonia is produced during the bacterial digestion of proteins in the gut, is absorbed into the portal circulation, and usually undergoes extensive degradation in the liver.⁹² Most researchers believe that encephalopathy is caused by products, such as ammonia, derived from the gastrointestinal tract that are usually metabolized by the liver. These agents reach the peripheral circulation as a result of poor hepatic metabolism or through portosystemic shunts that may be physiologic or the result of surgical procedures. In patients with cirrhosis, in addition to the accumulation of ammonia in the blood, the permeability of the brain to ammonia appears to be increased.⁹³ Other suggested etiologic agents for hepatic encephalopathy include γ -aminobutyric acid, endogenous benzodiazepines,⁹⁴ branched-chain amino acids (e.g., tryptophan),⁹⁵ neurotoxic short-chain fatty acids, mercaptans, phenols,⁹⁶ and endogenous opiates.⁹⁷

The following observations suggest that ammonia is the key mediator in hepatic encephalopathy: (a) ammonia levels are increased in 80% to 90% of patients with the condition,⁹⁸ (b) factors that precipitate hepatic encephalopathy cause increases in ammonia levels, and (c) treatments that relieve hepatic encephalopathy lower ammonia levels.⁹⁹ Arguments against this hypothesis include the following: (a) levels of ammonia correlate poorly with the severity of hepatic encephalopathy, (b) high ammonia levels alone do not cause encephalopathy, (c) administration of ammonia to patients with cirrhosis but not hepatic encephalopathy does not cause encephalopathy, and (d) treatments that reduce ammonia levels also reduce the levels of other putative toxins.⁹⁹

Clinical Features. A wide range of neurologic symptoms may occur in patients with hepatic dysfunction. Subtle deficits may include changes in personality, memory loss, alterations in sleep patterns, and minor decreases in intellectual function. Defects may be detectable only by detailed psychometric testing. If no known underlying liver disease is suspected, establishing the cause of an alteration in mental status may be difficult.

With progression of disease, asterixis, a rapid repetitive flexion-extension of the wrist that occurs in response to sustained extension of the forearm and fingers, may occur. In addition, stigmata of liver disease are usually evident, including fetor hepaticus and spider angiomas. The combination of asterixis, elevated ammonia levels, and altered mental status in a patient with known liver disease strongly suggests the diagnosis. Electroencephalographic changes are nonspecific and may occur in patients with a variety of other conditions.

Factors that commonly precipitate hepatic encephalopathy include impaired renal function, variceal hemorrhage, constipation, infection, excessive dietary protein, and drugs, especially benzodiazepines and barbiturates.

Treatment. Treatment options for hepatic encephalopathy include correction of the precipitating factors, alterations in diet, bowel cleansing, medications that reduce ammonia production and neutralize its effects, and medications to treat possible neurotransmitter and nutrient deficiencies.

A search for precipitating factors is imperative and includes cultures of urine, sputum, and ascitic fluid; determination of electrolyte abnormalities; screening for viral infection; assessment of overall volume status; drug history; and endoscopy (Table 58.7).

Therapy begins with a trial of volume expansion via intravenous hydration to relieve azotemia and reduce concentrations of toxic substances by dilution. The mainstays of treatment are directed at the removal of nitrogenous compounds from the gut. Most ammonia is produced within the small and large bowel by bacterial metabolism of dietary and endogenous protein. Orally administered cathartics and enemas are the best methods to achieve bowel cleansing, and these are combined with marked dietary restriction of protein.¹⁰⁰

^aArousal effect in selected patients may be secondary to enhanced renal function.

^bHigh cost and equivocal benefits of intravenous amino acid mixtures make it difficult to justify routine use.

The cathartic of choice is lactulose, a nonabsorbable disaccharide that reaches the distal ileum and colon essentially unmetabolized. Many theories regarding the mechanism of action of lactulose have been proposed. Initially, the presumed mechanism of action was that on reaching the colon, lactulose is metabolized by colonic bacteria to acidic products that lower the pH of the colon. Lowering the pH inhibits the growth of ammonia- and urea-producing bacteria and promotes the growth of *Lactobacillus*, a bacterium with little proteolytic activity.¹⁰¹ The validity of this theory has been questioned. It appears now that lactulose alters the metabolism of intestinal bacteria by providing carbohydrate, which enhances the bacterial uptake of ammonia.¹⁰² Combined with the osmotic diarrhea caused by the cathartic activities of lactulose, this effect leads to an increased excretion of ammonia.

The dosage of lactulose, 45 to 90 g/d, is administered orally, divided into three or four doses. The dosage can be adjusted to produce two or three soft stools daily. Hourly doses of 30 to 45 mL can be used to induce more rapid improvement during the initial phase of therapy. Symptoms usually abate within 24 hours, but more than 48 hours may be required. Doses can be adjusted if side effects such as flatulence, diarrhea, and electrolyte abnormalities occur.

Nonabsorbable antibiotics have also been used to decrease the number and concentration of ammonia-forming bacteria in the gut. Most experience has accrued for neomycin and metronidazole. These antibiotics are active against gram-negative anaerobes such as *Bacteroides*, which are considered to be a major source of ammonia production.^{103,104} The dosage of neomycin, 2 to 8 g/d, is divided into four doses and is continued for 4 to 10 days. Multiple double-blinded, randomized trials have determined the efficacy of antibiotics alone or in com-

bination with lactulose. For acute hepatic encephalopathy, studies have shown that neomycin for 4 days is equally as effective as lactulose,¹⁰⁵ and metronidazole for 7 days is as effective as neomycin.¹⁰⁶ In addition, for chronic hepatic encephalopathy, neomycin for 10 days was equal to lactulose.¹⁰¹ Although only small amounts (1% to 3%) of neomycin are absorbed, a risk for nephrotoxicity and ototoxicity still exists.¹⁰⁷ Rifaximin, a macrolide antibiotic not approved for use in the United States, has similar efficacy when compared with lactulose and neomycin.¹⁰⁸

PORTAL HYPERTENSION

- 8** Portal hypertension is defined as a portal vein pressure above the normal range of 5 to 8 mm Hg. Portal hypertension may also be defined by the hepatic vein–portal vein pressure gradient, which is greater than 5 mm Hg in portal hypertensive states.¹⁰⁹ Pressures in the portal venous system are usually measured indirectly via the wedged hepatic venous pressure. The technique is similar to that used to determine pulmonary capillary wedge pressure by pulmonary arterial (Swan-Ganz) catheterization.

Anatomy

The venous anatomy of the portal system is relatively constant, with the “usual” anatomy present in 98% of the population (Fig. 58.5). The portal vein is formed by the confluence of the superior mesenteric and splenic veins behind the neck of the pancreas. The inferior mesenteric vein most often joins the splenic vein before the portal vein is formed, but approximately one third of the time the inferior mesenteric vein joins the superior mesenteric vein. The superior mesenteric vein may not be present, and the portal vein may be formed by multiple small branches from the mesenteric system that join the splenic vein.

Many branches of the portal venous system are affected when portal pressure rises. As pressure increases, blood flow decreases and the pressure in the portal system is transmitted to its branches. This transmission of pressure through branches of the portal system is beneficial in that it decreases overall portal pressure. It also is responsible for many of the complications of portal hypertension, however, because of the resulting dilation of venous tributaries.

The coronary or left gastric vein becomes highly significant in portal hypertension, by diverting portal blood to the veins of the lesser curve of the stomach and the esophagus, leading to the formation of varices. Other important collaterals include the inferior mesenteric vein, which connects with its rectal branches, which, when distended, form hemorrhoids; the umbilical vein in the ligamentum teres of the falciform ligament, which joins the left portal vein and causes abdominal wall veins around the paraumbilical plexus to dilate (caput medusae); the short gastric veins, branches of the splenic vein, which communicate with gastric veins and contribute to gastric varices; and the retroperitoneal veins of Retzius, which communicate with the gastrointestinal veins through the bare areas of the liver where no peritoneal layer separates the abdominal viscera from the retroperitoneum. The retroperitoneal collaterals can also form large splenorenal shunts that may decompress the portal system but are associated with severe encephalopathy.

Physiology

As in any vascular bed, portal hypertension is the product of blood flow and resistance. In nearly all cases, portal hypertension is caused by increased resistance to portal blood flow

FIGURE 58.5. Potential venous collaterals that develop with portal hypertension. The veins of Sappey drain portal blood through the bare areas of the diaphragm and through paraumbilical vein collaterals to the umbilicus. The veins of Retzius form in the retroperitoneum and shunt portal blood from the bowel and other organs to the vena cava.

secondary to cirrhosis, portal vein thrombosis, or hepatic venous obstruction, though in rare instances, an arterioportal fistula may cause flow-related hypertension. Normally, the liver offers little resistance to portal flow because of the porous nature of the hepatic sinusoids and the capacity of the organ to expand. Moreover, the liver has no intrinsic control over portal blood flow; it is merely a passive recipient of splanchnic flow, the primary regulation of which occurs at the level of the splanchnic arterioles.¹¹⁰ As discussed earlier, the deposition of collagen in the space of Disse (capillarization), in addition to the contractile properties of stellate cells, causes an increased resistance to portal blood flow in cirrhosis. In addition, various cytokines and hormones contribute to elevated portal pressures by inducing splanchnic vasodilation and an increase in splanchnic flow.

The increased blood flow through collateral vessels and subsequently increased venous return cause the characteristic hemodynamic features of portal hypertension, which include an increase in cardiac output and total blood volume and a decrease in systemic vascular resistance.¹¹¹ Arteriovenous shunts within the liver, stomach, and small intestine contribute to the augmented venous return and decreased peripheral vascular resistance. Early in the course of portal hypertension, blood pressure may be normal, but with progression of disease, blood pressure usually falls.¹¹²

The portal venous concentration of nitric oxide, a potent vasodilator, has been shown to be elevated in patients with cirrhosis and portal hypertension.¹¹³ In addition to nitric oxide,

many other vasodilators are elevated in portal hypertension, including prostacyclin, endotoxin, and glucagon.¹¹⁴

Etiology

Many pathologic processes can cause portal hypertension (Table 58.8). These are usually classified as prehepatic, hepatic, or posthepatic (presinusoidal, sinusoidal, or postsinusoidal) conditions. As noted above, in prehepatic and posthepatic conditions, portal hypertension is the result of mechanical venous obstruction at the level of the portal or hepatic veins, respectively, whereas cirrhosis is the main cause of hepatic portal hypertension.

Budd-Chiari Syndrome and Veno-occlusive Disease.

The Budd-Chiari syndrome is caused by hepatic venous obstruction. The name of the syndrome is derived from two investigators, the first of whom (Budd)¹¹⁵ described the classic presentation of abdominal pain, ascites, and hepatomegaly, and the second of whom (Chiari)¹¹⁶ described the pathologic characteristics of the liver. The obstruction may occur at the level of the inferior vena cava, the hepatic veins, or the central veins within the liver itself and may be the result of congenital webs (most common in Africa and Asia), acute or chronic thrombosis (most common in the West), and malignancy. With occlusion of the hepatic veins, pressure increases in the central veins. As a result, centrilobular congestion, necrosis, and, with

 Splenomegaly

chronic disease, fibrosis and cirrhosis with portal hypertension develop.

In the West, the most common causes of this syndrome are hypercoagulable states associated with polycythemia vera, myeloproliferative disorders, paroxysmal nocturnal hemoglobinuria, and defects in the coagulation cascade, as in conditions associated with high estrogen levels (e.g., pregnancy, use of birth control pills).^{117,118} Neoplasms may cause hepatic venous obstruction by direct invasion and occlusion of the vessels, or by establishment of a prothrombotic milieu secondary to the malignancy itself. In the East, the major causes of obstruction of the vena cava and hepatic veins are membranous webs that directly occlude the vessels. The etiology of vena cava webs is unknown.

Veno-occlusive disease is characterized by obliterative endophlebitis of the intrahepatic veins (see Table 58.3). Causes

of veno-occlusive disease include medications, toxins, and pyrrolizidine alkaloids.

Budd-Chiari syndrome may present with acute, subacute, or chronic symptoms and is often misdiagnosed. This is unfortunate, because early treatment will prevent the development of hepatic fibrosis, which can lead to end-stage liver disease. Nearly 50% of patients have had symptoms for more than 3 months.^{119,120} Acute symptoms include hepatomegaly, right upper quadrant abdominal pain, nausea, vomiting, and ascites. In the chronic form of the disease, patients may present with the sequelae of cirrhosis and portal hypertension, including variceal bleeding, ascites, spontaneous bacterial peritonitis, fatigue, and encephalopathy. In the chronic form, the entire liver atrophies except for the caudate lobe, which may hypertrophy because its hepatic vein(s) enters the vena cava separately, so that venous outflow is not impeded.⁶⁷ The hypertrophy of the caudate lobe creates a longitudinal narrowing of the retrohepatic vena cava, which is surrounded by parenchyma, leading to secondary obstruction of the caval flow in the abdomen.

The diagnosis is most often made by ultrasonographic evaluation of the liver and its vasculature, which has a sensitivity of 85% to 95%.¹¹⁷ Duplex scanning may reveal the location of the obstruction and characterize the flow within the vena cava and hepatic, portal, mesenteric, and splenic veins. Cross-sectional imaging using contrast-enhanced CT or MRI is helpful in defining the entire abdominal venous circulation and assessing the status of the liver and its individual lobes, which is essential in planning therapy. Traditionally, the “gold standard” for the diagnosis has been angiography, which provides detailed information on the location and degree of obstruction.

The management of patients with this syndrome has traditionally been surgical intervention. Liver biopsies are usually performed preoperatively. The response rates to medical therapy, which does not relieve the obstruction to portal outflow, are poor, and survival rates without surgical intervention are approximately 10%. Antithrombotic agents may be used in the rare patient who presents early with acute venous occlusion. Although major surgery has been favored in the past, including meso-atrial shunting^{121,122} and even liver transplantation,¹²³ minimally invasive approaches are now preferred.¹²⁴ The mainstay of therapy is mechanical decompression with a side-to-side portosystemic shunt, optimally achieved with a percutaneous portocaval shunt. After shunt placement, the pressure on the vena cava by the caudate lobe is gradually relieved, leading to restoration of liver function.

A more direct solution, which is necessary in the face of complete caval obstruction, is the creation of a mesoatrial shunt, which was described by Cameron and Maddrey.¹²¹ This radical procedure has been largely supplanted by percutaneous portocaval shunting (transjugular intrahepatic portosystemic shunt [TIPS]). The rates of postprocedural encephalopathy are usually not increased in patients with Budd-Chiari syndrome, because they have anatomically healthy livers that recover fully if decompression is achieved early prior to the establishment of cirrhosis. In patients with end-stage liver disease, liver transplantation may be performed.¹²³ The 5-year survival rate for patients with good hepatic function before the shunt procedure is approximately 60%, with a 34% to 88% survival for patients after liver transplantation.¹²⁵ Postoperatively, patients are treated with long-term anticoagulation to prevent recurrent thrombosis.

As noted, minimally invasive treatment using TIPS may be first-line therapy, and it has supplanted surgical shunting in our practice.^{126,127} Case reports and small series have suggested efficacy for this technique,¹²⁸ and a recent larger study has indicated 1- and 5-year survival rates of 93% and 74%, respectively.¹²⁹ Many patients develop shunt occlusion, however, and further angiographic manipulation and long-term anticoagulation are required to maintain patency.

Portal Vein Thrombosis. Portal vein thrombosis is commonly associated with advanced cirrhosis, and may be the ominous portent of a hepatocellular carcinoma. Spontaneous portal vein thrombosis in the absence of cirrhosis is the cause of portal hypertension in fewer than 10% of adult patients but is the most common cause in children.¹³⁰ In contrast to patients with cirrhosis-induced portal hypertension, these patients have normal liver function and are not as susceptible to the development of complications, such as encephalopathy. Causes of portal vein thrombosis include umbilical vein infection (the most common cause in children), coagulopathies (protein C and antithrombin III deficiency), hepatic malignancy, myeloproliferative disorders, inflammatory bowel disease, pancreatitis, trauma, and previous splenorenal shunt.¹³¹ Most cases in adults are idiopathic.

The diagnosis can be made by sonography, which reveals an echogenic lesion in the lumen of the portal vein and an absence of portal venous flow on duplex examination.¹³² With time, cavernous transformation of the portal vein may occur, in which channels develop within the clotted portal vein.¹³⁰ CT and MRI are also useful in establishing the diagnosis. Often, the initial manifestation of portal vein thrombosis is variceal bleeding in a noncirrhotic patient with normal liver function. Splenomegaly is another common finding.

The initial therapeutic option for the control of hemorrhage caused by portal vein thrombosis is esophageal variceal ligation. If unsuccessful, the distal splenorenal shunt has been the traditional surgical treatment for patients with isolated portal vein thrombosis. In patients whose intrahepatic portal vein is patent (most commonly children), however, a shunt created by placing an internal jugular vein graft between the superior mesenteric vein and the patent left portal vein within the parenchyma of the liver (Rex shunt) may be the optimal therapeutic procedure for reestablishing physiologic portal flow.¹³³ This is the most elegant solution for portal obstruction because the portal pressure is reduced by restoring blood flow to the liver, preventing chronic hepatic atrophy and dysfunction, which can occur in a patient with long-standing portal decompression. In fact, in our practice, the Rex shunt is the

first-line treatment and we reserve splenorenal shunting for patients who have no remnant intrahepatic portal system to receive the shunted blood.

Splenic Vein Thrombosis. Splenic vein thrombosis is most often caused by disorders of the pancreas, including acute and chronic pancreatitis, trauma, pancreatic malignancy, and pseudocysts. This association is related to the location of the splenic vein behind and close to the pancreas. Other causes include retroperitoneal masses, abscesses, and inflammatory bowel disease; the remaining cases are idiopathic. Gastric varices are present in approximately 80% of patients, and esophageal varices in 30% to 40%.¹³⁴ Isolated “sinistral” or left-sided portal hypertension occurs in the setting of normal liver function, and patients are readily cured with splenectomy, although observation for asymptomatic patients is acceptable. The main indication for splenectomy is variceal hemorrhage.

Complications of Portal Hypertension

The most important complications of portal hypertension are gastrointestinal bleeding secondary to esophageal and gastric varices, ascites, and hepatic encephalopathy. The mortality risk associated with portal hypertension is primarily related to the functional status of the cirrhotic liver. Child introduced a scoring system of liver function for the purposes of assessing prognosis after portosystemic shunt surgery in patients with cirrhosis, which has been subsequently modified several times to the *Child-Turcotte-Pugh (CTP) score* (Table 58.9). These indices incorporate clinical and laboratory data as a means to assess the functional status of the liver, estimate hepatic reserve, and predict morbidity and mortality. They had been adopted by the United Network for Organ Sharing (UNOS) as a tool for stratifying pretransplant mortality risk for patients on the waiting list for liver transplantation.¹³⁵ Over the last decade, the use of these criteria in transplant have been replaced by the Model for End-stage Liver Disease (MELD)

TABLE 58.9

CLASSIFICATION

CHILD-TURCOTTE CRITERIA FOR HEPATIC FUNCTIONAL RESERVE

■ CRITERION	■ CLASS A	■ CLASS B	■ CLASS C
Encephalopathy	None	Minimal	Advanced
Ascites	None	Easily controlled	Poorly controlled
Bilirubin (mg/dL)	<2	2–3	>3
Albumin (g/gL)	>3.5	3–3.5	<3
Nutrition	Excellent	Good	Poor, “wasting”
Child-Turcotte-Pugh Grading of Severity of Liver Disease			
Score	1	2	3
Encephalopathy	None	1 or 2	3 or 4
Ascites	None	Mild	Moderate
Bilirubin (mg/dL)	1–2	2.1–3	≥3.1
Albumin (g/dL)	≥3.5	2.8–3.5	≤2.7
Prothrombin time (s)	1–4	4.1–6	≥6.1
or INR	<1.7	1.7–2.3	>2.3
Grade A, 5–6; grade B, 7–9; grade C, 10–15			

INR, international normalized ratio.

score, which uses serum bilirubin, creatinine, and the international normalized ratio (INR) to produce a surprisingly robust prediction of 90-day mortality for patients with cirrhosis on the transplant list.¹³⁶ Though the CTP score produces a more complete assessment of the patient, its use of subjective clinical elements in the score made it unreliable as a verifiable element in assessment compliance with center behavior in national organ transplant policy.^{137,138}

While the MELD score was initially developed for the prognosis of patients after TIPS, the CTP score has had long-standing use as a reliable predictor of mortality risk for shunt surgery and, by extension, mortality risk of patients with cirrhosis undergoing other types of abdominal surgery.^{139,140} Patients with normal function, termed “Child A,” have adequate hepatic reserve and survival rates similar to those of noncirrhotic patients, whereas Child C patients have mortality rates in excess of 50% and may not tolerate any intervention short of hepatic transplantation.

Varices. One of the most life-threatening complications of portal hypertension is bleeding from esophageal varices. Esophageal varices are dilated veins found most commonly in the distal 5 cm of the esophagus. In the normal esophagus, a venous plexus is located in the submucosa; it becomes more superficially located to the lamina propria in the distal esophagus.^{141–143} This more superficial location in the distal esophagus is consistent with the known increased occurrence of bleeding varices in that location. In addition, 10% to 15% of patients with esophageal varices have gastric varices.

The pressure in the portal system is an important determinant of the likelihood for varices to develop. As noted earlier, portal pressure may be estimated from the hepatic vein wedge pressure, and the gradient between the wedge pressure and the free hepatic vein pressure is an indirect measure of the resistance across the liver. In general, varices do not develop in persons with hepatic vein–portal vein gradients below 12 mm Hg. Pressure gradients above 12 mm Hg are invariably present in patients with varices, but this pressure does not necessarily produce varices in all patients. Other, undetermined factors must play a role. The prevalence of varices in patients with cirrhosis varies from 25% to 70%, depending on the severity of their liver disease.

In approximately 10% of all patients presenting with acute upper gastrointestinal bleeding, esophageal varices are the cause of bleeding. Rates of bleeding from varices vary among studies. In a study of the natural history of varices in which patients were prospectively followed for 6 years, esophageal varices developed in approximately 8% of patients with cirrhosis each year during the first 2 years of observation; the percentage increased to 30% by 6 years. Of the patients who had small varices detected at initial endoscopy, large varices developed in 25%.¹⁴⁴ Other studies show an incidence of varices of up to 90% for patients with cirrhosis.^{145,146} Once varices are present, bleeding occurs in 25% to 35% of cases, with the highest risk occurring within the first year after diagnosis.^{146,147} Of patients who survive an episode of bleeding, 30% experience rebleeding within 6 weeks, and 70% at 1 year.^{147,148} The correlation between severity of varices and derangement of hepatic function is inconstant, so mortality rates from bleeding varices range from 5% to 50%, with rates of 5%, less than 25%, and more than 50% for Child A, B, and C patients, respectively.¹⁴⁸

The propensity for varices to bleed has been extensively studied. When combined with clinical data such as the presence of active alcohol consumption, certain endoscopic characteristics of varices have been correlated with initial episodes of bleeding (Table 58.10). These factors include variceal size, Child-Pugh class, and the presence of red wale markings (longitudinal dilated venules that resemble whip marks).¹⁴⁶ Direct and indirect measurements of portal pressure have been used

to predict the likelihood of bleeding, with hemorrhage occurring only in patients with portal–hepatic venous gradients above 12 mm Hg.^{149,150}

Prevention of Initial Variceal Bleeding. Because of the severe consequences of variceal bleeding, methods to prevent first (primary prophylaxis) and recurrent (secondary prophylaxis) episodes of bleeding have been developed. These include control of the underlying cause of cirrhosis (i.e., alcohol consumption) and pharmacologic and surgical interventions to lower portal pressure. The next section discusses methods of primary prophylaxis to prevent initial episodes of bleeding (Table 58.11).

Beta Blockade. Use of nonspecific β -adrenergic blockade has been studied extensively in randomized controlled trials of the primary prophylaxis of variceal bleeding. The mechanism of action of these drugs (propranolol, nadolol) involves effects of both β_1 -adrenergic and β_2 -adrenergic blockade, including decreased cardiac output and increased splanchnic arteriolar vasoconstriction as a result of the loss of opposing β_2 -adrenergic dilation.^{150,151} The combined effects decrease portal blood flow and subsequently portal pressure.

These drugs are effective in portal hypertension associated with prehepatic, intrahepatic, and posthepatic conditions,¹⁵² regardless of whether ascites is present.¹⁵³ Not all patients respond to therapy, however. Two meta-analyses have evaluated seven randomized controlled trials comparing propranolol or nadolol with placebo in the prevention of initial variceal bleeding. Both analyses concluded that beta blockade is significantly correlated with a reduced incidence of bleeding.^{154,155} A reduction of 40% was noted overall after all trial results were combined, with bleeding developing in approximately 16% of treated and 27% of untreated patients. The goal of therapy is to reduce the hepatic vein–portal vein gradient to below 12 mm Hg or to more than 20% below baseline.¹⁵⁶

In addition to reducing the number of first episodes of bleeding, beta blockade therapy has been shown to reduce mortality in most clinical trials.¹⁵⁷ However, the differences were significant in only one study. A meta-analysis of these studies concluded that mortality from bleeding is reduced in patients with large varices.

TABLE 58.11

TREATMENT

PREVENTION/TREATMENT OPTIONS FOR VARICEAL BLEEDING

■ DRUG	■ DOSE
Propranolol	10–20 mg bid titrated weekly to maximum of 160 mg bid
Nadolol	20 mg orally qd, titrated to reduction of HR by 20%–25%, absolute HR of 55–60, symptoms
Isosorbide-5-mononitrate	20 mg orally tid
Vasopressin with nitroglycerin	0.4 U/min to maximum of 1.0 U/min, titrated to maintain SBP at approximately 100 mm Hg
Octreotide	50-mg bolus, followed by 50 mg/h for 5 d or until definitive treatment

HR, heart rate; SBP, systolic blood pressure.

Nitrates. Organic nitrates such as isosorbide-5-mononitrate, a vasodilator, have been used to reduce portal pressures. The possible mechanisms of action may include the following: (a) reflex splanchnic vasoconstriction secondary to peripheral venodilation and venous pooling; (b) decreased collateral resistance by arterial vasodilation; and (c) decreased intrahepatic resistance, possibly as a result of inhibition of stellate cell contractility.¹⁵⁸ These agents may be used alone in patients with contraindications to beta-blocker therapy, such as chronic obstructive pulmonary disease and congestive heart failure, or in combination with beta blockade in patients who do not have contraindications but respond inadequately to beta-blocker therapy alone. Studies have indicated an enhanced reduction of portal pressure and a decreased incidence of bleeding in patients who receive combination therapy.¹⁵⁹ In the only study that compared combination therapy with beta-blocker therapy alone, approximately 8% of patients treated with the combined regimen experienced bleeding, compared with 18% of patients treated with beta-blocker therapy alone.¹⁶⁰ Thus, combination therapy may become the mainstay for prevention of bleeding in cirrhotic patients with varices.

Surgical Intervention. In the 1950s and 1960s, surgeons created prophylactic portosystemic shunts in an attempt to prevent variceal bleeding. These procedures were studied in a randomized controlled fashion and, although effective in preventing variceal bleeding, they caused an increased incidence of hepatic failure and encephalopathy and had no effect on overall survival.^{160,161} These results provided clinical support for the notion that portal diversion accelerated the decline of liver function in patients with cirrhosis and they are no longer performed for this indication.

Endoscopic Sclerotherapy and Variceal Ligation. In the past, prophylactic sclerotherapy to prevent variceal bleeding was an accepted practice. An increased mortality in alcoholic patients treated with sclerotherapy, however, has been seen. Technical challenges of endoscopic sclerotherapy (ES) and esophageal and pulmonary complications have led to abandonment of ES for the primary prevention of variceal bleeding. Initial investigations of the effectiveness of endoscopic variceal ligation (EVL) as a method of primary prophylaxis to prevent initial bleeding in high-risk patients with esophageal varices reported mixed results.^{162,163} In one study, no statistically significant differences in the incidence of initial bleeding and mortality were found in a comparison of patients after variceal ligation with controls,¹⁶⁴ though subgroup analysis revealed a significant decrease in the incidence of initial bleeding for Child-Pugh class B patients.¹⁶³

Furthermore, there seems to be a significant prognostic divergence related to variceal size. As data have accumulated, consensus recommendations regarding prophylaxis have emerged as presented in recent practice guidelines from the American Association for the Study of Liver Diseases (AASLD). Briefly summarized, patients with cirrhosis with small, low-risk varices should be managed with beta-blocker prophylaxis. Variceal ligation may be most appropriately indicated in primary prophylaxis in patients who do not tolerate beta-blocker therapy. Patients with high-risk varices need to be managed with pharmacologic protection supplemented by EVL, and the specific protocol of variceal obliteration is proposed in the guidelines.¹⁶⁴

Treatment of Esophageal Variceal Bleeding

Initial Management. Initial management of the patient with acute variceal bleeding includes the following: (a) establishment and maintenance of an airway; (b) hemodynamic monitoring; (c) placement of large-bore intravenous lines; (d) full laboratory investigation, including measurement of hemoglobin and hematocrit, coagulation profile, liver function tests, measurement of electrolytes, and assessment of renal function; (e) administration of blood products as needed, including packed red cells, platelets, and fresh frozen plasma; and (f) intensive care unit monitoring.

Pharmacologic Therapy. Administration of vasoactive medications can be commenced almost immediately after patient presentation if the history and physical findings suggest variceal bleeding. This practice decreases the rate of bleeding and enhances the endoscopic ability to visualize the site(s) of bleeding.

Vasopressin (antidiuretic hormone) has potent splanchnic vasoconstrictive properties that decrease portal venous and collateral flow and reduce portal pressure. In randomized prospective trials, as well as in a meta-analysis, continuous intravenous administration of vasopressin has proved to reduce variceal bleeding, an observation initially made in 1962.^{165–167} When vasopressin was compared with placebo, bleeding stopped in an average of 52% of patients who received vasopressin and 18% of patients who received placebo. Rates of rebleeding as high as 45% were noted, however. Because of coronary vasoconstrictive effects, vasopressin is often used in combination with a vasodilator, such as nitroglycerin. The combination provides protection from adverse cardiac events and increases the effectiveness of vasopressin by decreasing intrahepatic and collateral resistance.¹⁶⁸ A meta-analysis of three randomized controlled trials confirmed the

FIGURE 58.6. Techniques of intravariceal (A) and paravariceal (B) injection of esophageal varices.

increased effectiveness of vasopressin and nitroglycerin in comparison with vasopressin alone.¹⁶⁹ Somatostatin and octreotide, its longer-acting eight-amino-acid derivative, have been used extensively for the treatment of variceal bleeding. These agents decrease splanchnic blood flow indirectly by reducing the levels of other factors, such as glucagon, vasoactive intestinal peptide, and substance P, rather than by direct vasoconstriction.¹⁷⁰ The effects of somatostatin are limited to the splanchnic circulation, so that side effects are minimized.¹⁷¹ A somatostatin and octreotide combination has proved to be as effective as vasopressin, sclerotherapy, and balloon tamponade in multiple studies.^{172–174} Because of the lack of complications related to somatostatin therapy, octreotide is the initial drug of choice for the treatment of acute variceal hemorrhage.

Endoscopic Interventions. Esophageal variceal ligation has become the principal approach to the initial control and ongoing treatment of variceal bleeding; it is performed at the bedside in acute bleeding and has replaced variceal sclerosis in recent years. The technique of sclerotherapy (Fig. 58.6) entails performing upper gastrointestinal endoscopy with a flexible endoscope, visualizing the varices, and injecting 1 to 5 mL of sclerosing agent into or in close proximity to each varix. Sclerosing agents include sodium morrhuate, ethanolamine, polidocanol, and sodium tetradecyl sulfate. Total injection volume is 20 to 30 mL. The injections are begun at the distal esophagus and are continued circumferentially and proximally until all clinically relevant varices have been injected. Complications of sclerotherapy occur in 10% to 30% of patients and include fever, retrosternal chest pain (most common), dysphagia, and, more significantly, perforation with mediastinitis, bleeding from sclerosant-induced ulcers, esophageal stenosis, and sepsis. Overall, the treatment-related mortality rate is less than 2%. In the approximately 1% of patients in whom perforation occurs, the mortality rate may be as high as 50%. Success rates for initial control of variceal bleeding by endoscopy range from 60% to 90%, but more than one session is required to stop bleeding completely in up to 95% of cases.^{175,176}

The technique of ligation (Fig. 58.7) includes placing an endoscope over a sheath (which allows multiple insertions and removal of the endoscope), suctioning of a varix into the lumen of a plastic channel, and then placing a rubber band around the tissue. The procedure is similar to the ligation of

hemorrhoids. The tissue then sloughs in 1 to 3 days, leaving a shallow ulcer. Up to six bands can be placed at each session. Newer endoscopes allow for the placement of multiple bands without removal of the endoscope. The placement of bands follows the same pattern as in sclerotherapy.

Success rates for variceal ligation range from 80% to 100%, in comparison with 77% to 94% for sclerotherapy, in controlled trials.¹⁷⁷ A meta-analysis that examined these data and compared the results of seven randomized controlled trials indicated an equal or better success rate for variceal ligation than for sclerotherapy in eliminating esophageal variceal bleeding, with fewer complications. When patients who underwent ligation therapy were compared with patients who underwent sclerotherapy, a reduction of approximately 50% in the incidence of rebleeding (50% vs. 25%) and death from bleeding (17% vs. 10%) and a reduction of 30% in overall

FIGURE 58.7. Endoscopic ligation of esophageal varices. The device used for ligation is based on the standard Barron-type ligator for the treatment of anal hemorrhoids. The esophageal varix is drawn up into the ligating device with suction (A), and the base of the varix is ligated with an O-ring (B). Up to six varices can be treated at a single session.

FIGURE 58.8. The Sengstaken-Blakemore tube is used to tamponade acutely bleeding gastroesophageal varices. The tube has three lumina—one to aspirate the stomach, another to inflate the gastric balloon, and a third to inflate the esophageal balloon. Patients treated with balloon tamponade should be in an intensive care unit, and endotracheal tubes should be placed in almost all to prevent aspiration.

mortality (32% vs. 24%) were noted in the ligation group.¹⁷⁸ In addition, the incidence of esophageal stricture, bleeding from treatment-related ulceration, and the number of treatment sessions were decreased with ligation. In patients with profuse bleeding, the type of endoscope used for variceal ligation may make visualization of the bleeding varices difficult. Some investigators choose to perform sclerotherapy in these patients and use variceal ligation once bleeding is somewhat controlled.

Balloon Tamponade. The vast majority of patients (75% to 90%) with bleeding esophageal varices respond to endoscopic or pharmacologic therapy. For patients who fail these interventions, balloon tamponade (Fig. 58.8) is an alternative therapy with a high success rate in controlling bleeding. It entails the placement of a specialized nasogastric tube with two balloons that can be inflated separately and to different pressures to apply direct compression to the gastroesophageal junction and the esophagus. Once the mainstay in the initial management of variceal bleeding, use of these tubes is becoming a lost art, most suitable for initial stabilization of patients in a facility with limited availability of endoscopic or radiologic support. Because these tubes are difficult to use, and may cause fatal complications with esophageal injury, it remains important for surgeons and gastroenterologists with responsibility for managing gastrointestinal bleeding to understand principles for safe use. The most commonly used tubes are the Sengstaken-Blakemore tube and the Minnesota tube. The former consists of a gastric balloon and an esophageal balloon with a sump port for gastric suctioning. The latter tube has an additional port above the esophageal balloon for the aspiration of saliva and other material from the esophagus and pharynx.

Placement of these tubes begins with the establishment of a safe airway by endotracheal intubation. The tube is then

passed through the nose and into the stomach. Radiographic confirmation that the tip of the tube is in the stomach is required before balloon inflation to prevent inadvertent intraesophageal inflation of the gastric balloon and resultant perforation. The gastric balloon is inflated with 200 mL of air and firmly pulled backward against the gastroesophageal junction to tamponade any proximal gastric bleeding. The esophageal balloon is then inflated to a pressure of 30 to 40 mm Hg, and the tube is secured to the patient by means of a face mask or helmet to ensure adequate stability of the tube and prevent inadvertent removal.

Because of the possible complications of balloon tamponade (e.g., aspiration, esophageal and gastric perforation, necrosis), which occur in 10% to 20% of patients, its use is restricted to approximately 24 hours. Success rates for cessation of bleeding are 70% to 80%, but more than half of all patients rebleed when the balloons are deflated. Although this method is highly effective in the initial control of bleeding, with an efficacy similar to that of pharmacologic agents, because of its transient effects it can be used only as a temporizing measure in anticipation of a more definitive procedure (e.g., TIPS, placement of a surgical shunt, or transplantation) and is used only after endoscopic and pharmacologic therapies have failed.

Transjugular Intrahepatic Portosystemic Shunt. In the 10% to 20% of patients who continue to bleed or who have early rebleeding, a shunt procedure (to bypass the high-pressure hepatic vascular bed) may be indicated. The mortality rate associated with failure to control bleeding can be as high as 90%, and surgically created shunts in this setting are associated with a high morbidity and mortality rate.

The transjugular intrahepatic portosystemic shunt (Fig. 58.9) has become first-line treatment for bleeding esophageal varices when the aforementioned attempts fail.¹⁷⁹ After ultrasonographic confirmation of patency of the portal vein, the procedure is performed in the interventional radiology suite, where a wire-guided stent (8 to 12 mm in diameter) is placed percutaneously into the jugular vein. The wire is then guided through the superior vena cava, right atrium, and inferior vena cava into a hepatic vein, after which the catheter traverses the hepatic parenchyma and joins the hepatic vein to a portal vein. This connection effectively creates a side-to-side portacaval shunt. Success rates in the cessation of variceal bleeding are as high as 90% to 100%, with an incidence of recurrent bleeding of approximately 10%.^{180,181}

As discussed earlier, the ideal portosystemic shunt lowers the pressure in the portal system without critically reducing liver perfusion, which may cause hepatic dysfunction and may accelerate the progression of cirrhosis. It is possible to readily measure the portal pressure during TIPS, and many authors have proposed these measurements as a guide to optimal management of the TIPS to balance control of bleeding with hepatic perfusion. To control bleeding, the therapeutic goal is to reduce the hepatic–portal venous pressure gradient to below 12 mm Hg. TIPS reduces the portosystemic pressure gradient to a mean of approximately 9 to 15 mm Hg (average, 10 mm Hg) or to 40% to 62% below baseline.^{182–184} A recent study has indicated that a residual portal gradient less than 5 mm Hg is associated with a deleterious impact on hepatic flow.¹⁸⁵ Earlier studies documented high mortality (40% to 60% at 6 to 7 weeks) despite the relative noninvasiveness of the procedure, reflecting the gravity of the clinical condition of most patients requiring this intervention. One potential cause of the high mortality is a delay in instituting TIPS until multiple unsuccessful attempts at sclerotherapy or banding have been made. Since well-validated instruments predict the survival of patients after TIPS, the procedure should be used with caution in patients with high MELD scores, though TIPS has been used successfully to bridge patients to transplantation.^{186,187} The use of TIPS in massive variceal bleeding in a patient with a high

FIGURE 58.9. Schematic representation of the steps used to create a transjugular intrahepatic portosystemic shunt. (From Zemel G, Katzen BT, Becker GJ, et al. Percutaneous transjugular portosystemic shunt. *JAMA* 1991;266:390, with permission.)

MELD score who has contraindications to liver transplant should be regarded as a palliative intervention.

As with all portosystemic shunts, a significant complication of TIPS is the development of hepatic encephalopathy. After placement of a TIPS, the incidence of hepatic encephalopathy rises from 10% before treatment to 25%,¹⁸⁸ and the incidence of progression to accelerated liver failure is approximately 3% to 5%.

Although in early series stenoses or occlusion of the stent developed in up to 50% to 60% of patients in the first year, long-term patency can be maintained by ongoing surveillance

of the shunt with redilatation, as needed. Shunt stenosis is managed angiographically with thrombolytic therapy, dilation, or replacement of the stent. The newest shunts are lined with polytetrafluoroethylene (PTFE) and have a much higher patency than the original permeable Wallstents.¹⁸⁹ Patients are usually followed at 3-month intervals by ultrasonography to assess the patency of the shunt. At 6 months of follow-up, 92% of patients had had no episodes of rebleeding, and 82% were free of hemorrhage at 1 year. It is safe to assert that the TIPS is now the standard procedure used to halt bleeding in patients who fail medical therapy. The ability to effectively

FIGURE 58.10. End-to-side portacaval shunt, also referred to as an Eck fistula. The portal vein is divided, the hepatic limb of the portal vein is ligated, and the splenic end of the portal vein is anastomosed end to side to the vena cava. All portal blood is necessarily diverted into the vena cava, and the hepatic limb of the portal vein cannot serve as an outflow tract.

FIGURE 58.11. Side-to-side portacaval shunt. An anastomosis is made between the side of the portal vein and the side of the inferior vena cava. With a shunt of standard diameter, almost all splanchnic blood is diverted around the liver into the low-pressure vena cava. The hepatic limb of the portal vein serves as an outflow tract from the liver toward the low-pressure vena cava.

decompress the portal circulation without open surgery in these critically ill patients has transformed clinical hepatology. Patients become medically stable and can be evaluated for transplantation electively. Patients with reversible liver disease (e.g., abstinent alcoholics) may recover fully without further intervention because the TIPS will slowly close as the liver heals.

Surgical Decompression

Background. Surgeons have been performing shunt procedures since the 1800s. The first was an end-to-side portacaval shunt with ligation of the distal portal vein, performed by Nicolai Eck (Eck fistula) in dogs. In 1945, Whipple and Blakemore at the Columbia-Presbyterian Medical Center in New York performed this shunt for the first time for the indication of variceal bleeding.¹⁹⁰ This group was also responsible for the development of the tube for the tamponade of bleeding esophageal varices, which adopted the name of Blakemore, as discussed previously.

- 11** Surgical interventions for the treatment of bleeding varices are divided into three main types: (a) liver transplantation, (b) shunt procedures, and (c) devascularization procedures. The only definitive procedure for the treatment of portal hypertension caused by cirrhosis is orthotopic liver transplantation, and the success of this option during the past two decades has revolutionized the treatment of portal hypertension and its complications in patients with end-stage liver disease. However, for the treatment of portal hypertension in patients without cirrhosis or in those whose liver function does not warrant

a transplant (e.g., patients with portal vein thrombosis), decompressive surgically created shunts or devascularization procedures may be performed.

Shunts. Portosystemic shunts created operatively can be divided into three categories: (a) totally diverting shunts, (b) partially diverting shunts, and (c) selective shunts. Total shunts are created by completely bypassing the flow of blood away from the liver by joining the portal vein to the vena cava. Examples include the end-to-side portacaval shunt (Eck fistula) (Fig. 58.10) and the large-diameter (>10 mm) side-to-side portacaval (Fig. 58.11), mesocaval, and central splenorenal shunts. Because the pressure in the portal vein is much higher than that in the vena cava (or the renal vein), large side-to-side shunts divert all blood flow through the path of least resistance, so that flow in the portal vein is reversed, creating “hepatofugal” flow, out of the liver and decreasing total hepatic perfusion. One of the causes of ascites in patients with portal hypertension is high pressure at the level of the hepatic sinusoids with protein-rich fluid leaking directly out of the swollen liver. The main difference between end-to-side and side-to-side shunts is that maintenance of high pressure with end-to-side shunts may worsen ascites, whereas side-to-side procedures effectively relieve this problem by reducing sinusoidal pressure. Complete portal blood flow diversion lowers portal pressure and is highly effective in the treatment of bleeding esophageal varices but, as noted earlier, may accelerate hepatic decompensation.

The main complications of totally diverting shunts are a worsening of liver function and hepatic encephalopathy as a

FIGURE 58.12. Interposition mesocaval shunt. A plastic prosthesis or an autogenous internal jugular vein is used for the shunt. One end is anastomosed to the inferior vena cava, and the other end is anastomosed to the trunk of the superior mesenteric vein. The shunt curves around the lower edge of the third portion of the duodenum and is sometimes called a C-shunt.

result of decreased flow through the liver and loss of hepatotropic factors from the mesenteric venous system. Another disadvantage of portocaval shunts is that the porta hepatis must be dissected, so that future surgical procedures in the area (e.g., liver transplantation) are more difficult.

Partially diverting shunts allow for the maintenance of hepatopetal flow while decompressing the high pressures in the portal system. The original shunts were larger than 10 mm in diameter and were able to create a gradient between the portal vein and vena cava that maintained some prograde hepatic flow. All these shunts, however, dilated over time and became complete shunts in that the portal vein-to-inferior vena cava pressure gradient disappeared. The small-diameter (8-mm) side-to-side mesocaval (Fig. 58.12) and portacaval (Sarfeh) (Fig. 58.13) shunts are performed with an interposition graft made of either expanded PTFE or Dacron. A significant component of the Sarfeh procedure is ligation of the coronary (left gastric), gastroepiploic, and other collateral veins. Bleeding from varices resolves in more than 90% of patients.^{191,192} This smaller-diameter shunt has a higher resistance than the larger shunt, is synthetic and therefore does not dilate, can maintain hepatic perfusion, and is associated with a lower incidence of hepatic encephalopathy. With these shunts, portal pressure gradients can be reduced to the critical 12 mm Hg while hepatopetal flow is maintained in up to 80% to 90% of patients. In addition, the maintenance of mesenteric pressure at or relatively close to normal levels may prevent the hyperammonemia associated with total shunts. One relatively common complication is graft thrombosis, which occurs in up

to 16% of patients.¹⁹² Shunt thrombosis can usually be treated angiographically. Dissection at the porta hepatis leads to the formation of adhesions, which may compromise later liver transplantation.

Selective shunts are designed to create two separate drainage systems within the portal venous network. A high pressure is maintained within the mesenteric system and a low pressure is created in the esophagogastric system by shunting blood from the latter into the systemic circulation without decompressing the mesenteric network. The most traditional and most favored selective shunt is the distal splenorenal shunt (Fig. 58.14).¹⁹³ The distal splenorenal shunt selectively decompresses the gastroesophageal venous system through an anastomosis between the distal end of the splenic vein and the side of the renal vein. Decompression occurs through the short gastric veins, which are in continuity with the splenic vein. In addition, as in the small side-to-side shunts described earlier, collateral veins must be ligated.

Advantages to this procedure are the following: (a) control of bleeding is excellent in more than 90% of patients, (b) no dissection of the porta hepatis is required, (c) hepatopetal flow is maintained, and (d) the incidence of encephalopathy (5% to 24%) and the risk of progressive liver failure is lower.¹⁹⁴ Experience with this shunt has revealed that most patients have hepatopetal flow, with 84% of alcoholic and 90% of nonalcoholic patients having prograde flow at 4 years after surgery.¹⁹⁵ Some loss of prograde portal flow does occur as a result of either portal vein thrombosis (approximately 10% of patients) or increased flow through collaterals located along the pancreas. This latter mechanism can be prevented by complete dissection of the splenic vein from the posterior aspect of the pancreas (splenopancreatic disconnection),¹⁹⁶ but this additional technique adds to the complexity of the operative procedure and to the incidence of complications.

The distal splenorenal shunt is relatively contraindicated in patients with significant ascites. Because no portal venous decompression occurs, ascites may increase after a distal splenorenal shunt is created. In addition, ligation of collateral vessels and lymphatics during the procedure contributes to increased portal pressures and subsequent increase in ascites. Patients with small splenic veins (<8 mm) have a relatively high incidence of shunt thrombosis.

Several trials comparing side-to-side total shunts with the distal splenorenal shunt found that they are equally effective (>90%) in stopping variceal hemorrhage.¹⁹⁷ The incidence of hepatic encephalopathy is lower after the distal splenorenal shunt, with rates of 36% and 15% for the total and selective shunts, respectively. Rates of rebleeding were similar and ranged from zero to 30%, with no survival advantage for either procedure.

Investigators have also used the side-to-side nonselective total shunt for the emergency treatment of bleeding varices. Bleeding stopped in more than 90% of patients with medical therapy alone, although bleeding often restarted shortly thereafter. Bleeding stopped in all patients after surgery, and 99% of patients were completely free of episodes of rebleeding. The 5-year survival was approximately 80%, with the majority of deaths occurring during the first year after surgery as a result of progressive hepatic failure. Hepatic encephalopathy requiring recurrent intervention, including dietary restriction and lactulose or neomycin therapy, occurred in 8% of patients. These data support an aggressive, systematic approach to caring for these patients before, during, and after surgery, though most of these patients had alcoholic liver disease, which recovers rapidly with withdrawal of the alcohol.

Devascularization Procedures. Devascularization procedures are nonshunting techniques in which the venous drainage of the stomach and esophagus is disconnected from the liver and intestinal vessels. These procedures are relatively less technically demanding than shunting procedures and can be performed in

FIGURE 58.13. Small-diameter interposition portacaval Sarfeh shunt. A vascular prosthesis measuring 8 to 10 mm in diameter is interposed between the side of the vena cava and the side of the portal vein. The goal is to reduce portal pressure partially and thereby prevent variceal hemorrhage but still maintain sufficient pressure to permit the prograde flow of portal blood to the liver. This procedure is simpler to perform than that for the Warren shunt and theoretically avoids the problem of diversion of an increasing proportion of portal blood away from the liver over time, as occurs with the Warren shunt.

FIGURE 58.14. Distal splenorenal Warren shunt. The splenic vein is divided near its junction with the superior mesenteric vein. The distal end of the splenic vein is anastomosed to the renal vein. Varices are selectively decompressed through the stomach and short gastric veins into the splenic vein and then into the vena cava through the renal vein. Portal hypertension is maintained in the portal and superior mesenteric veins to provide enough pressure to drive portal blood through the diseased liver.

FIGURE 58.15. Transection and reanastomosis of the distal esophagus with the stapling device to control variceal hemorrhage. **A:** A stapling device is inserted through a small gastrotomy incision. **B:** When the device is fired, the esophagus is simultaneously transected and reanastomosed with staples. **C:** If the device fires correctly, a complete ring of esophageal tissue is excised.

patients with extensive portal thromboses that preclude other options. They do not interfere with hepatopetal blood flow and therefore do not increase the incidence of hepatic encephalopathy.

The procedures range in complexity from simple esophageal transection and reanastomosis with an end-to-end anastomosis (EEA) stapler combined with ligation of the coronary vein (Fig. 58.15) to the Sugiura procedure (Fig. 58.16). The Sugiura procedure requires both abdominal and thoracic incisions, through which a splenectomy, devascularization of the proximal stomach and esophagus, transection of the esophagus with reanastomosis, and ligation of all gastroesophageal collaterals are performed.¹⁹⁸ The latter procedure can also be performed via a single abdominal incision.¹⁹⁹ Bleeding recurs in fewer than

5% of patients in Japan, but rates of rebleeding range from 10% to 54% in other countries.²⁰⁰ Operative mortality rates range from 10% to 35% and outcomes are certainly related to the severity of liver disease. In our practice, these procedures are not used in patients with liver disease, but exclusively in patients with diffuse portomesenteric thrombosis, in whom decompressive shunts cannot be made.

Hepatic Transplantation. Liver transplantation is the definitive therapy for portal hypertension and cirrhosis and the complications thereof, but is indicated for the overall management of end-stage liver disease and has no role in the control of acute variceal bleeding. When successful, transplantation treats both the underlying disease and any acute complication.

FIGURE 58.16. Sugiura esophageal transection and devascularization operation.

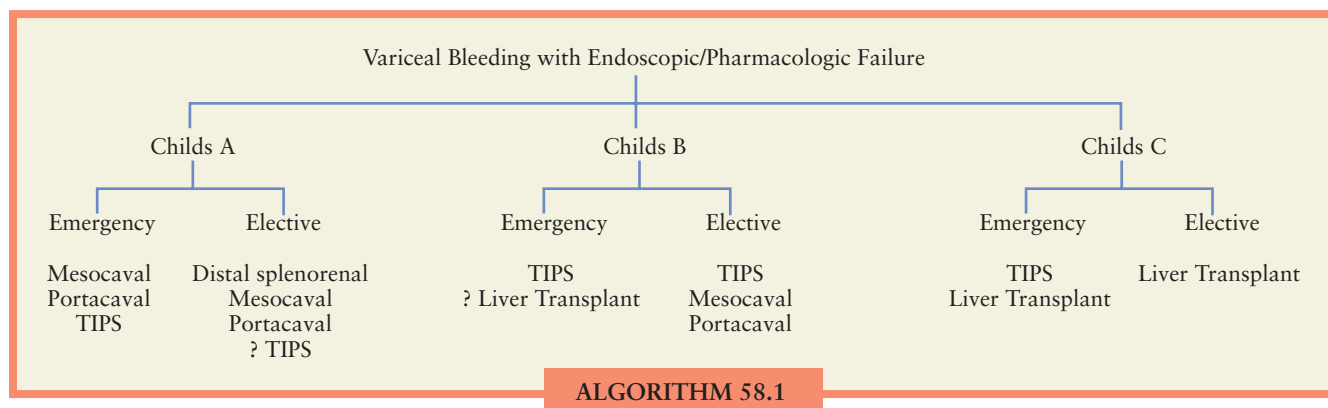

Algorithm for the Treatment of Variceal Bleeding. Treatment recommendations assume the following: (a) adequate expertise in all aspects of caring for cirrhotic patients, including expert endoscopy and interventional radiology; (b) the availability of trained surgeons capable of performing the indicated surgical procedures; and (c) the availability of hepatic transplantation or transfer to a center where it is available (Algorithm 58.1).

Resuscitation and Primary Control. At presentation, patients should immediately undergo resuscitation and hemodynamic monitoring, followed by establishment of the diagnosis of variceal bleeding. A pharmacologic agent should be commenced immediately in the emergency department, consisting of octreotide or beta blockade, or both. Second-tier agents include vasopressin and nitroglycerin. Upper gastrointestinal endoscopy should be performed expeditiously in the appropriate setting to attempt variceal ligation. Sclerotherapy is a sec-

ond choice. Rapid triage is imperative, and repeated attempts at endoscopic therapy in the setting of continued bleeding may lead to worsening of the patient's overall status and increased morbidity and mortality. For the majority of patients (75% to 90%), these interventions will be effective in controlling the hemorrhage. If rebleeding occurs, another attempt at endoscopic therapy is warranted while preparations are made for decompressive therapy in the event of treatment failure. In the relatively small number of patients in whom primary control is not achieved, balloon tamponade is usually the next immediate procedure of choice to stop the hemorrhage, albeit temporarily.

Definitive Control. The failure of primary measures mandates definitive interventions, which include TIPS, surgical shunts, or devascularization procedures with urgent evaluation for liver transplantation candidacy in patients not previously known to the transplant team. These methods introduce

ALGORITHM 58.1. Suggested treatment options, in order of preference, for patients who fail medical management for variceal bleeding.

permanent mechanical alterations that may adversely affect liver function and are of varying practical utility in the emergency setting. Proper decision making requires primary stratification based on hepatic function and secondary stratification according to treatment setting (emergent vs. elective). It is critical that the issue of eligibility for hepatic transplantation be addressed before these interventions are undertaken because portal decompression can provoke hepatic failure. In patients who are not transplant candidates, the development of post-operative hepatic failure is a lethal event, and this must be discussed in detail with patients before intervention.

The question of which of the various types of surgical procedures should be used for emergency variceal bleeding has been studied in multiple trials. The number of publications on a given topic is not necessarily correlated with the general applicability of a specific surgical intervention and may reflect the referral pattern or hospital system in which the studies were performed. As in all complex operative procedures, the technical ability of an individual surgeon to perform a given procedure is crucial to its success and is correlated with complications. The following recommendations are based on the assumption that well-trained surgeons are performing these procedures.

Patients with well-compensated liver function (Child A) rarely fail to respond to pharmacologic and endoscopic therapy. Patients who continue to bleed should undergo TIPS, particularly if they are potential transplant candidates. TIPS does not disturb surgical anatomy and avoids the technical difficulty associated with transplantation in patients with previous shunts of any type. The rare patients with anticipated long-term survival without a transplant may be candidates for a distal splenorenal shunt. Excellent results have also been reported in this setting with small-diameter portacaval H-graft shunts. The arguments for the H-graft are that it is technically easier to perform and provides excellent control of bleeding. In addition, it is associated with high rates of long-term maintenance of prograde portal flow and patency and low rates of hepatic encephalopathy and mortality. Similar arguments can be made for the small-diameter mesocaval H-graft shunts. Mesocaval shunts have the added advantage of eliminating the need for portal dissection and subsequent adhesion formation.

In the hemodynamically unstable Child A cirrhotic patient, TIPS is the procedure of choice. If this is not an option, a non-selective side-to-side portacaval or mesocaval shunt can be performed for immediate control of bleeding, though this approach has been used only once in the last decade in hundreds of bleeding patients in our center. For patients who are noncompliant or live far from tertiary care medical centers capable of performing and maintaining the TIPS, a simple operation such as the side-to-side shunt, which requires comparatively little follow-up, may be more appropriate.

Child B patients with cirrhosis with high-risk varices who have failed endoscopic treatment are best treated with TIPS. If TIPS is technically impossible, a shunt may be considered for patients with contraindications to liver transplantation.

For Child C patients with cirrhosis with refractory bleeding, the options are much more limited. These patients should undergo TIPS, with the expectation that liver function will deteriorate and hepatic encephalopathy may worsen unless urgent transplant can be performed. In nontransplant candidates who fail nonoperative therapy and continue to bleed, TIPS may be lifesaving in the short term, but many patients will die of progressive liver failure.

Currently, the only indication for devascularization procedures is the presence of extensive thrombosis in the portal vessels, which precludes the use of a shunt.

In conclusion, open surgical intervention short of liver transplantation for patients with cirrhosis and portal hypertension is becoming a rarity. With the advent of TIPS, the indications for surgically created shunts are dwindling. Although

some studies have shown an increased need for reintervention in patients who have undergone TIPS for variceal bleeding, the overwhelming efficacy and safety of TIPS has essentially settled the issue and today, even in large liver centers, open portal decompressive procedures are rarely performed.

Prevention of Recurrent Variceal Bleeding. The risk for rebleeding in untreated patients with a history of prior variceal bleeding ranges from 47% to 70%, with an associated mortality rate of 20% to 70%. The risk factors for subsequent bleeding from esophageal varices are the same as those for initial bleeding and include continued alcohol abuse, size of varices, Child class, and the presence of red markings on endoscopic evaluation.

Multiple randomized trials,¹⁸⁹ including a meta-analysis, have shown a reduction in rebleeding rates with the use of beta-blocker therapy in comparison with placebo. Mortality rates were reduced in most of those trials. All patients without a contraindication to beta-blocker therapy should be treated with one of these agents. In addition, combination therapy with beta blockade and nitrates reduces rates of rebleeding in comparison with either agent alone.²⁰¹

As indicated in the section on treatment of bleeding varices, endoscopic variceal ligation has surpassed sclerotherapy in stopping bleeding. Moreover, in preventing rebleeding, variceal ligation has proved to be at least as effective as sclerotherapy, with fewer complications, and has become the endoscopic intervention of choice.

Almost 10 randomized trials have been performed to compare endoscopic intervention with TIPS.^{202,203} The vast majority of data support the use of TIPS, which is associated with significantly decreased rates of rebleeding (approximately 25% less) and no increase in mortality. Because the incidence of significant encephalopathy is doubled, however, TIPS should be reserved for patients who fail other means of therapy.

In the older literature, many randomized trials have compared endoscopic sclerotherapy with elective shunt surgery to prevent recurrent bleeding from esophageal varices, but the importance of this comparison is now nearly irrelevant. The majority used the distal splenorenal shunt. Rates of rebleeding varied from 3% to 17% for shunts and from 35% to 60% for sclerotherapy, with no difference in overall survival. For good-risk patients without medically intractable ascites, the distal splenorenal shunt appears to be a better option to prevent recurrent variceal bleeding than repetitive sclerotherapy. TIPS is readily chosen in the face of recurrent bleeding in the setting of failed endoscopic therapy.

Gastropathy and Gastric Varices. Approximately 10% of patients with esophageal varices also have gastric varices. Conversely, about 90% of patients with gastric varices have esophageal varices.²⁰⁴ Bleeding from gastric varices occurs in approximately 25% of affected patients, is usually more severe than bleeding from esophageal varices, and is poorly controlled by sclerotherapy. Rebleeding occurs in up to 30% of patients after an initial bleed.²⁰⁵ The same pharmacologic interventions used for esophageal varices are used to treat gastric varices. Balloon tamponade may also be used. TIPS is the primary therapy for controlling gastric varices with the distal splenorenal shunt for the rare patient who cannot receive TIPS.

Portal hypertensive gastropathy is a condition characterized by dilation of the venules and capillaries of the gastric mucosa without associated inflammation. The major complication of gastropathy is bleeding; gastropathy accounts for 4% to 38% of all episodes of acute bleeding in patients with cirrhosis.²⁰⁶ TIPS may provide therapeutic decompression in this setting as well.

Ascites. One of the most important consequences of hepatic dysfunction in cirrhosis and portal hypertension is ascites.

TABLE 58.12 **DIAGNOSIS****DIFFERENTIAL DIAGNOSIS OF ASCITES**

Portal Hypertension

- Cirrhosis and other intrahepatic diseases
- Hepatic congestion
 - Congestive heart failure
 - Constrictive pericarditis
 - Inferior vena cava obstruction
 - Budd-Chiari syndrome
- Portal vein occlusion

Hypoalbuminemia

- Nephrotic syndrome
- Protein-losing enteropathy
- Malnutrition

Miscellaneous Disorders

- Myxedema
- Ovarian disease (Meigs syndrome, struma ovarii)
- Peritoneal carcinomatosis
- End-stage renal disease
- Chylous ascites
- Bile ascites
- Urine ascites

From Sleisenger MH, Fordran JS. *Gastrointestinal Disease: Pathophysiology, Diagnosis and Management*, 4th ed. Philadelphia, PA: WB Saunders; 1989:433.

This development portends a significant worsening of the patient's condition, with markedly decreased survival rates. Ascites is defined as the accumulation of free fluid within the abdominal cavity (normally <150 mL). Causes of ascites are listed in Table 58.12. In cirrhosis, the fluid is derived from a combination of hepatic (high in protein) and splanchnic (low in protein) lymph that cannot be absorbed as a result of the increased hydrostatic pressures within the liver and splanchnic systems secondary to cirrhosis and capillarization of the space of Disse.²⁰⁷ Because of the loss of sinusoidal fenestrations and a subsequent decrease in their permeability, splanchnic lymph is more abundant than hepatic lymph in patients with advancing cirrhosis, so that the protein content of ascitic fluid is relatively low.²⁰⁸ The main underlying pathophysiology in the development of ascites is renal sodium retention and associated water retention, which lead to fluid overload. Peripheral vasodilation and lower pressures are thought to be secondary to the dilator effects of nitric oxide, glucagon, and prostaglandins on nascent arteriovenous shunts present throughout the splanchnic vascular system, as well as in muscle, skin, and brain. The severity of liver disease is not uniformly correlated with the presence or absence of ascites.

Clinical and Laboratory Features. Ascites may be present in patients with cirrhosis who have no other overt signs or symptoms. Patients may present with subtle signs of weight gain and an inability to fit into clothes. Physical examination reveals shifting dullness to percussion (1.5 L of ascitic fluid), fluid waves (10 L), and bulging flanks.²⁰⁹ With progression of disease and massive ascites, respiratory status may be compromised secondary to increased intra-abdominal pressure and pleural effusions, which are often present and usually

located on the right side. The progression may be slow or more rapid after an inciting event, such as a variceal bleed or infection.

Stigmata of poor liver function include peripheral muscle wasting, palmar erythema, spider angiomas, peripheral edema, a palpable liver, and caput medusae (dilated periumbilical veins). With progressive ascites and increased abdominal pressure, umbilical and inguinal hernias often develop and may be difficult to manage. Abdominal distention may be caused by gastrointestinal gas rather than ascites. Gas can be differentiated from fluid by eliciting hyperresonance to percussion, secondary to gas, as opposed to dullness with fluid. The most widely used test for the diagnosis of ascites is ultrasonography, which can also be helpful in determining the best location for therapeutic and diagnostic paracentesis.

Diagnostic Paracentesis. The differential diagnosis of ascites is presented in Table 58.12. Determination of the character of the ascitic fluid is helpful in establishing the diagnosis. Paracentesis may be performed in the midline, midway between the umbilicus and the pubic symphysis. The fluid from patients with cirrhosis is usually straw-colored and clear; measurements of protein (usually <2 g/dL), quantitative cell counts, and microbiologic culture and determination of pH, amylase, glucose, and albumin levels should be obtained. The serum-to-ascitic fluid albumin gradient (SAG) is calculated by subtracting the albumin concentration in ascites from the level found in serum. This gradient is helpful in determining the cause of ascites; high values (>1.1 g/dL) are generally associated with portal hypertension, whereas lower levels may be associated with other disorders, including malignancy.²¹⁰

Treatment. Initial therapy is usually directed at control of renal sodium and water retention, with bed rest and dietary manipulation. The upright position exacerbates sodium retention as a result of venous pooling and relative hypovolemia. Up to 15% of patients respond to this therapy alone with a natriuresis. A low-sodium diet is a critical part of the management of patients with cirrhosis (1 to 2 g of sodium per day or 45 to 90 mEq/d). A major problem with a strict low-sodium diet is lack of palatability and poor compliance. Fluid restriction is also an essential component of therapy in patients in whom hyponatremia develops (sodium concentration <125 mEq/L), with only 1,000 to 1,500 mL of fluid allowed each day.

For the 85% to 95% of patients who do not respond to bed rest and fluid and salt restriction, the mainstay of treatment is diuresis (Table 58.13). The loop diuretic furosemide and the potassium-sparing diuretic spironolactone are the two most widely used agents, and they can be combined to minimize side effects and maximize effectiveness. A diuresis of approximately 500 mL/d is the goal for patients with mild ascites and of up to 1 to 2 L/d for patients with both ascites and peripheral edema. More than 90% of patients respond to the combination of dietary manipulation and diuretics.^{209,211}

Complications of the use of spironolactone include painful breast enlargement in males, hyperkalemia, and metabolic acidosis. Complications of the more potent furosemide include prerenal azotemia, which occurs in approximately 20% of patients as a result of excessive diuresis and hypovolemia.²⁰⁹ Additional complications include hyponatremia and encephalopathy.

Large-volume paracentesis (removal of 4 to 6 L of ascitic fluid per day) and total paracentesis are techniques that can be used for patients with large amounts of fluid who are experiencing symptoms and are not responding to the aforementioned therapeutic endeavors. Patients requiring paracentesis usually have severe underlying liver disease and a 1-year survival rate of 25%.²¹² The technique of paracentesis involves placing a catheter into the abdominal cavity, either in the lower midline or in one of the lower quadrants. Care is taken

TABLE 58.13 **TREATMENT****TREATMENT OF ASCITES**

Bed rest
Sodium restriction
1–2 g/d (45–90 mEq/d)
Fluid restriction
1–1.5 L/d
Diuretics

400 mg/d for 6 mo
Trimethoprim/sulfamethoxazole
One double-strength tablet five times a week

to enter lateral to the rectus muscle and avoid the inferior epigastric artery. More than 30 L of fluid can be removed by means of total paracentesis, with 6 to 10 g of albumin infused for each liter of ascitic fluid removed.^{209,211,212} The albumin commonly is administered in the form of 25% albumin (12.5 g/50 mL). Controversy exists regarding the need for albumin replacement therapy in patients undergoing total paracentesis and repetitive large-volume paracentesis. Patients who have less than 5 L of ascitic fluid removed do not require albumin replacement.²¹³

The efficacy of paracentesis in the treatment of tense ascites has been studied extensively. Repetitive large-volume paracentesis has been shown to be as effective as diuretics in the treatment of moderate to severe ascites, with fewer systemic complications. A decreased length of hospital stay with no increase in the incidence of spontaneous bacterial peritonitis has been noted.²¹⁴ Paracentesis has become the therapy of choice for severe ascites.

Peritoneovenous shunts are surgically placed tubes that connect the peritoneal cavity with the superior vena cava via the internal jugular vein (Fig. 58.17). The two main types are the LeVeen shunt and the Denver shunt, both of which have a one-way valve that allows unidirectional movement of ascitic fluid from the peritoneal cavity into the systemic circulation. Although these shunts are effective in decreasing the volume of ascitic fluid, a significant number of major complications have been noted, including disseminated intravascular coagulation, heart failure, and sepsis,^{212,215} and associated mortality rates are high (approximately 20%).²¹⁶ The shunt is occluded in

FIGURE 58.17. LeVeen peritoneovenous shunt used for routing ascitic fluid into the systemic circulation. The shunt consists of fenestrated tubing for insertion into the peritoneal cavity, a one-way valve, and a length of venous tubing for insertion into the superior vena cava.

approximately 50% of patients at 1 year, and no improvement in survival is noted.²¹² The use of these shunts has drastically decreased with the development of the TIPS procedure. In addition to the use of TIPS, the placement of peritoneovenous shunts is now done percutaneously, further increasing the safety of these procedures.

Surgically created portosystemic shunts have been used in the past for the treatment of ascites. Because of high morbidity and mortality rates, an increase in encephalopathy and progression to liver failure, and the addition of the TIPS procedure to treatment options, surgically created shunts are now used infrequently for this indication alone. As discussed earlier, the TIPS is a total nonselective shunt that decompresses the portal system and reduces pressure at the hepatic sinusoids, thereby eliminating the drive for the production of ascitic fluid. In a study evaluating the use of TIPS for the treatment of medically refractory ascites, the ascites resolved completely in almost 75% of patients, and a partial response was noted in an additional 20%.²¹⁷ In addition, renal function improved during the 6 months of follow-up. TIPS in this group of patients, however, was associated with an increase in the number of cases of encephalopathy. Although survival appears to be unaffected by a TIPS procedure when compared with large-volume paracentesis, TIPS may simplify the

management of the patient while on the transplant waiting list.

- 12** Spontaneous bacterial peritonitis is a potentially lethal complication of portal hypertension with ascites that occurs in up to 10% of patients. The cause of spontaneous bacterial peritonitis is unknown. Antecedent gastrointestinal hemorrhage is common, and spontaneous bacterial peritonitis in this setting may be related to bacterial translocation from the gut. Deficits in immune function, both systemically and within the abdomen, including depressed²¹⁸ reticuloendothelial function,^{219–221} low ascitic protein concentration, and deficient ascitic opsonic activity, may play a role. Patients often present with abdominal pain and fever, but 10% to 20% of cases are discovered on routine paracentesis.^{222–224} In addition, patients may present with other signs not clearly related to spontaneous bacterial peritonitis, including worsening encephalopathy and deteriorating renal function. The diagnosis is easily made by examination of the ascitic fluid obtained by paracentesis. An elevated number of white blood cells ($>250/\text{mm}^3$) is diagnostic. The vast majority of cases of spontaneous bacterial peritonitis are caused by a single organism, most commonly gram-negative enteric bacteria. Hematogenous spread may lead to infection with *Streptococcus pneumoniae* (Table 58.14). If more than one organism is present, the diagnosis of spontaneous bacterial peritonitis must be questioned, and a search for intra-abdominal disease (secondary peritonitis), such as a perforated viscus or diverticulitis, should be performed.

The treatment of spontaneous bacterial peritonitis consists of supportive care and broad-spectrum antibiotics, most commonly cefotaxime, a third-generation cephalosporin. Protein replacement has been shown to significantly reduce mortality in patients with spontaneous bacterial peritonitis and is complementary to other interventions as established in the landmark publication from Barcelona.²²⁵ Other antibiotics with proved efficacy include ofloxacin, a quinolone. This antibiotic has potent activity against gram-negative organisms and reaches high levels in ascitic fluid. For patients who are clinically stable and able to take oral medications, this is the drug of choice. Cure can be achieved in 75% to 90% of cases, but mortality rates are high, ranging from 20% to 40%.^{226,227} The poor prognosis associated with spontaneous bacterial peritonitis warrants consideration of liver transplantation.

Prophylactic oral or intravenous antibiotics are indicated for two distinct groups of patients with cirrhosis with ascites: (a) those with gastrointestinal hemorrhage and (b) those with low protein counts in the ascitic fluid (<10 to 15 g/L).²²⁸ The antibiotics used in patients with hemorrhage are neomycin, colistin, and nystatin in combination, and ofloxacin alone. These antibiotics reduce the incidence of spontaneous bacterial peritonitis from approximately 15% to 20% to 3% to 9% and cause few side effects.^{229–231} A meta-analysis evaluating the use of prophylactic antibiotics in patients with gastrointestinal hemorrhage confirmed the utility of prophylaxis, with an approximately 30% decrease in the incidence of infection, a 20% decrease in the incidence of spontaneous bacterial peritonitis and bacteremia, and a 10% improvement in overall survival.²³² In patients with low protein levels in the ascitic fluid, multiple regimens have proved effective in reducing the incidence of spontaneous bacterial peritonitis, from approximately 20% to less than 5%.^{232–234}

Hernias and Ascites. Hernias of the anterior abdominal wall occur in up to 20% of patients with cirrhosis. The causes include increased intra-abdominal pressure and nutritional deficits, with muscular wasting and thinning of the fascia. If the hernias are left untreated, complications include incarceration, rupture, strangulation, and leakage. Patients with hernias and decompensated cirrhosis need to be evaluated for liver transplantation. In patients with stable liver function, hernias should be treated electively, with preoperative paracentesis to decrease intra-abdominal pressure. No increase in complication rates was noted in a study comparing the outcome of umbilical hernia repair in patients with and without ascites. A longer hospital stay and a significantly higher recurrence rate (73% vs. 14%) was noted, however, in the group of patients with ascites.^{235–237} We favor the use of abdominal drains to remove the ascites until the incision is healed, thereby preventing ascites from leaking through the wound. Meticulous fluid management is essential during the postoperative period to prevent early reaccumulation of ascites.

In patients with severe ascites, TIPS should be performed before hernia repair to ensure a good result. Emergency repair of hernias complicated by skin breakdown with ascites leak or incarceration or strangulation are managed in a similar fashion with preoperative large-volume paracentesis, and aggressive control of ascites postoperatively.

CHAPTER 59 ■ HEPATIC NEOPLASMS

CHRISTOPHER J. SONNENDAY, THEODORE H. WELLING, AND SHAWN J. PELLETIER

KEY POINTS

- 1 Evaluation of hepatic reserve, facilitated by assessment of the Child-Turcotte-Pugh classification and computed tomography volumetry, is essential to minimize the risk of postoperative liver failure following hepatectomy, particularly in patients with chronic liver disease and hepatic steatosis.
- 2 Surgical therapy of benign hepatic neoplasms should be confined to symptomatic patients and those patients with risk of malignant transformation (e.g., biliary cystadenoma, hepatic adenoma).
- 3 Treatment for hepatocellular cancer may include diverse modalities (resection, ablation, transplantation, systemic therapy), selected based on stage of disease and severity of underlying liver disease.
- 4 Liver transplantation for early-stage hepatocellular cancer can provide excellent patient survival, with long-term outcomes similar to patients undergoing liver transplantation for other indications.
- 5 Hepatic resection of colorectal metastases may be associated with 25% to 58% 5-year survival in appropriately selected patients. Patients most likely to benefit from metastasectomy include patients with small, solitary metastases and a prolonged disease-free interval since treatment of the primary tumor.
- 6 The number of hepatic neoplasms amenable to surgical therapy appears to be increasing in incidence, associated with increased diagnosis due to improved cross-sectional imaging, rising incidence of diseases (viral hepatitis, nonalcoholic fatty liver disease) associated with primary hepatic malignancies, and extension of surgical therapy to more patients with metastatic disease to the liver.
- 7 Portal vein embolization (PVE) prior to hepatic resection is an effective adjunct to increase the size of the future liver remnant, allowing expansion of major hepatectomy to patients with underlying liver disease. Failure to respond to PVE is a poor prognostic sign and contraindication to resection.
- 8 Laparoscopic liver resection has been demonstrated to be feasible and safe in properly selected patients, allowing extension of minimally invasive approaches to major hepatectomy and even living donor hepatectomy in highly experienced hands.
- 9 Advanced hepatobiliary techniques such as total vascular exclusion and hypothermic perfusion can be performed in select patients and experienced centers, allowing resection of tumors involving the inferior vena cava and/or hepatic veins with outcomes similar to other major hepatectomies.

The management of hepatic neoplasms is an increasingly complex and multidisciplinary area of medicine and surgery. Major hepatic resection, though an accepted therapy for appropriate indications, may carry significant risk of morbidity and mortality, especially in the setting of chronic liver disease. Increasingly, hepatic surgery is being performed by surgeons with subspecialty hepatobiliary and oncology training. Nevertheless, liver masses are commonly encountered by the general surgeon and proper management requires adherence to several key principles reviewed in the following text.

The surgical treatment of hepatic neoplasms was made possible by the evolution of understanding of hepatic physiology and anatomy over the past century. No person deserves more credit for the expansion of liver surgery than the French surgeon Claude Couinaud (Fig. 59.1).¹ He performed exhaustive anatomic studies of the segmental anatomy of the liver, facilitated by the examination of thousands of cadaver livers treated by injection of the common bile duct, hepatic artery, and portal and hepatic veins with polyvinyl acetate. Subsequent dissolution of the liver parenchyma with dilute acid left remarkable casts of the vascular and biliary anatomy of the liver. He subsequently translated his findings in the context of surgical procedures, identifying surface landmarks to segmental structures, describing the critical planes of the Glissonian sheaths, and identifying important anatomic variants that influenced the feasibility of resection procedures (Fig. 59.2).^{2,3} His published studies and observations, originally appearing in 1954 and continuing until his death in 2008, are required reading for surgeons who desire to understand surgical anatomy of the liver.

DIAGNOSIS

Hepatic neoplasms may present in a protean manner, ranging from incidental lesions found at the time of imaging for other indications, to profound hepatic dysfunction in patients with advanced liver disease and malignancy, to symptoms such as pain or jaundice influenced by tumor size and location. Regardless of the presentation, the initial diagnostic steps in the evaluation of a patient with a liver mass include assessment of hepatic synthetic function, precise anatomic review, and understanding of the oncologic context of the lesion(s) in question. These principles will be repeated throughout the following text, and guide decision making regarding the most appropriate therapy for a given neoplasm.

History, Physical Examination, and Laboratory Evaluation

Assessment of the patient with a new diagnosis of a hepatic mass or neoplasm should begin with consideration of any underlying chronic liver disease. By far, the most important risk factor for primary hepatic malignancies is chronic liver disease of any cause. Viral hepatitis remains the most common cause of chronic liver disease and cirrhosis worldwide, and we are in the midst of the peak of the hepatitis C epidemic in the United States. Importantly, many carriers of chronic hepatitis B and C infection remain unaware of their disease. The World Health Organization estimates that more than 500 million people

FIGURE 59.1. Claude Couinaud working with his collection of “liver casts” at the school of medicine in Paris, 1988. (Reprinted with permission from Francis Sutherland, MD, FSCRC.)

worldwide are infected with either hepatitis C (180 million) or hepatitis B (350 million).⁴ Assessment of a patient with a new liver mass should include viral serologic testing, even when risk factors for infection may not be obvious. Nonalcoholic fatty liver disease (NAFLD) is likely to be the next epidemic cause of chronic liver disease in the developed world,⁵ and it appears that primary liver cancer will remain an important potential conse-

quence of this disease as it is with other chronic hepatitis. Cholestatic liver disease, particularly primary sclerosing cholangitis (PSC), is a primary risk factor for cholangiocarcinoma, and the distinction between benign and malignant strictures can be especially troubling in the advanced stages of PSC.

A careful history about past liver disease and current symptoms is critical. Symptoms of chronic liver disease may be subtle in initial stages of the disease (fatigue, weight loss, muscle wasting), but may even be difficult to discern in more advanced cases (splenomegaly, bleeding diatheses, mild jaundice). Clearly, any symptoms of decompensated cirrhosis or portal hypertension should be cause for pause in the evaluation of a patient with a liver tumor. Encephalopathy, ascites, variceal hemorrhage, and progressive cholestasis are ominous signs that may pose prohibitive risk for hepatic resection or other procedures. Physical examination should also focus on eliciting signs of chronic liver disease such as skin changes, ecchymoses, splenomegaly, anasarca, or ascites. In patients with malignant disease, careful assessment for evidence of extrahepatic disease should be performed, with attention paid to lymphadenopathy, pleural effusions, or other mass lesions.

In addition to appropriate tumor markers when indicated, laboratory evaluation should include appraisal of hepatic synthetic function. A comprehensive metabolic panel to include measurement of bilirubin, albumin, and transaminases is important. Attention should be paid to renal function, which can be compromised with advanced liver disease and carries an especially poor prognostic value. A complete blood count is necessary, with special attention paid to the platelet count. Thrombocytopenia can be indicative of advanced hypersplenism and portal hypertension, which may translate to increased risk for hepatic resection and other procedures. Measurements of coagulation parameters, especially prothrombin time (PT) and the associated international normalized ratio (INR), are also sensitive indicators of hepatic synthetic function.

Evaluation of Hepatic Reserve

- 1** In patients with documented chronic liver disease, a more refined evaluation of hepatic synthetic function and reserve is necessary. In addition, a careful consideration of underlying

FIGURE 59.2. Couinaud’s segmental anatomy of the liver. Segments II, III, and IV make up the left lobe and segments V, VI, VII, and VIII constitute the right lobe. Segment I is the caudate lobe.

FIGURE 59.3. Perioperative complications and mortality among 1,803 patients undergoing hepatic resection at the Memorial Sloan Kettering Cancer Center (1991–2001), stratified by the number of hepatic segments resected. (Redrawn from Jarnagin WR, Gonen M, Fong Y, et al. Improvement in perioperative outcome after hepatic resection. *Ann Surg* 2002;236[4]:402.)

liver function should be performed in patients undergoing major hepatectomy (resection of three or more Couinaud segments), even in the absence of overt chronic liver disease, as the risk of perioperative morbidity and mortality rises substantially for such procedures (Fig. 59.3).⁶ While multiple modalities and strategies may be employed to evaluate hepatic reserve prior to liver resection, a reasonable algorithm is included in Algorithm 59.1 and reviewed here.

A number of clinical classification methods to assess underlying chronic liver disease have been developed, with the Child-Turcotte-Pugh (CTP) classification recognized universally (Table 59.1).⁷ Consensus exists that CTP class C patients should not undergo hepatic resection due to excessive perioperative morbidity and mortality, and CTP class B patients should only be considered for minor hepatic resections (resection of two or fewer Couinaud segments).^{8,9} The evaluation of CTP class A patients for hepatic resection is more difficult, as these patients can vary substantially in their risk of perioperative mortality and postoperative liver failure.

In recent years, the Model for End-Stage Liver Disease (MELD) score has been shown to accurately predict mortality among patients undergoing transjugular intrahepatic portosystemic shunt (TIPS) procedures,¹⁰ and is currently used in liver transplant allocation due to its accuracy in predicting transplant waitlist mortality.¹¹ Recently, investigators have advocated that MELD can be used to predict nontransplant surgical outcomes, particularly among cirrhotics undergoing hepatic resection.^{12,13} Among a population of CTP class A patients with hepatocellular carcinoma (HCC), perioperative mortality for patients with a MELD score greater than 9 was 29%, whereas there were no perioperative deaths among patients with a MELD score under 9.¹² However, a large multi-institutional study of Veteran's Affairs patients utilizing National Surgical Quality Improvement Project (NSQIP) data refuted the value of the MELD in risk stratification prior to hepatic resection, with CTP score and American Society of Anesthesiologists (ASA) class proving to be better predictors of perioperative complications and 30-day mortality.¹⁴

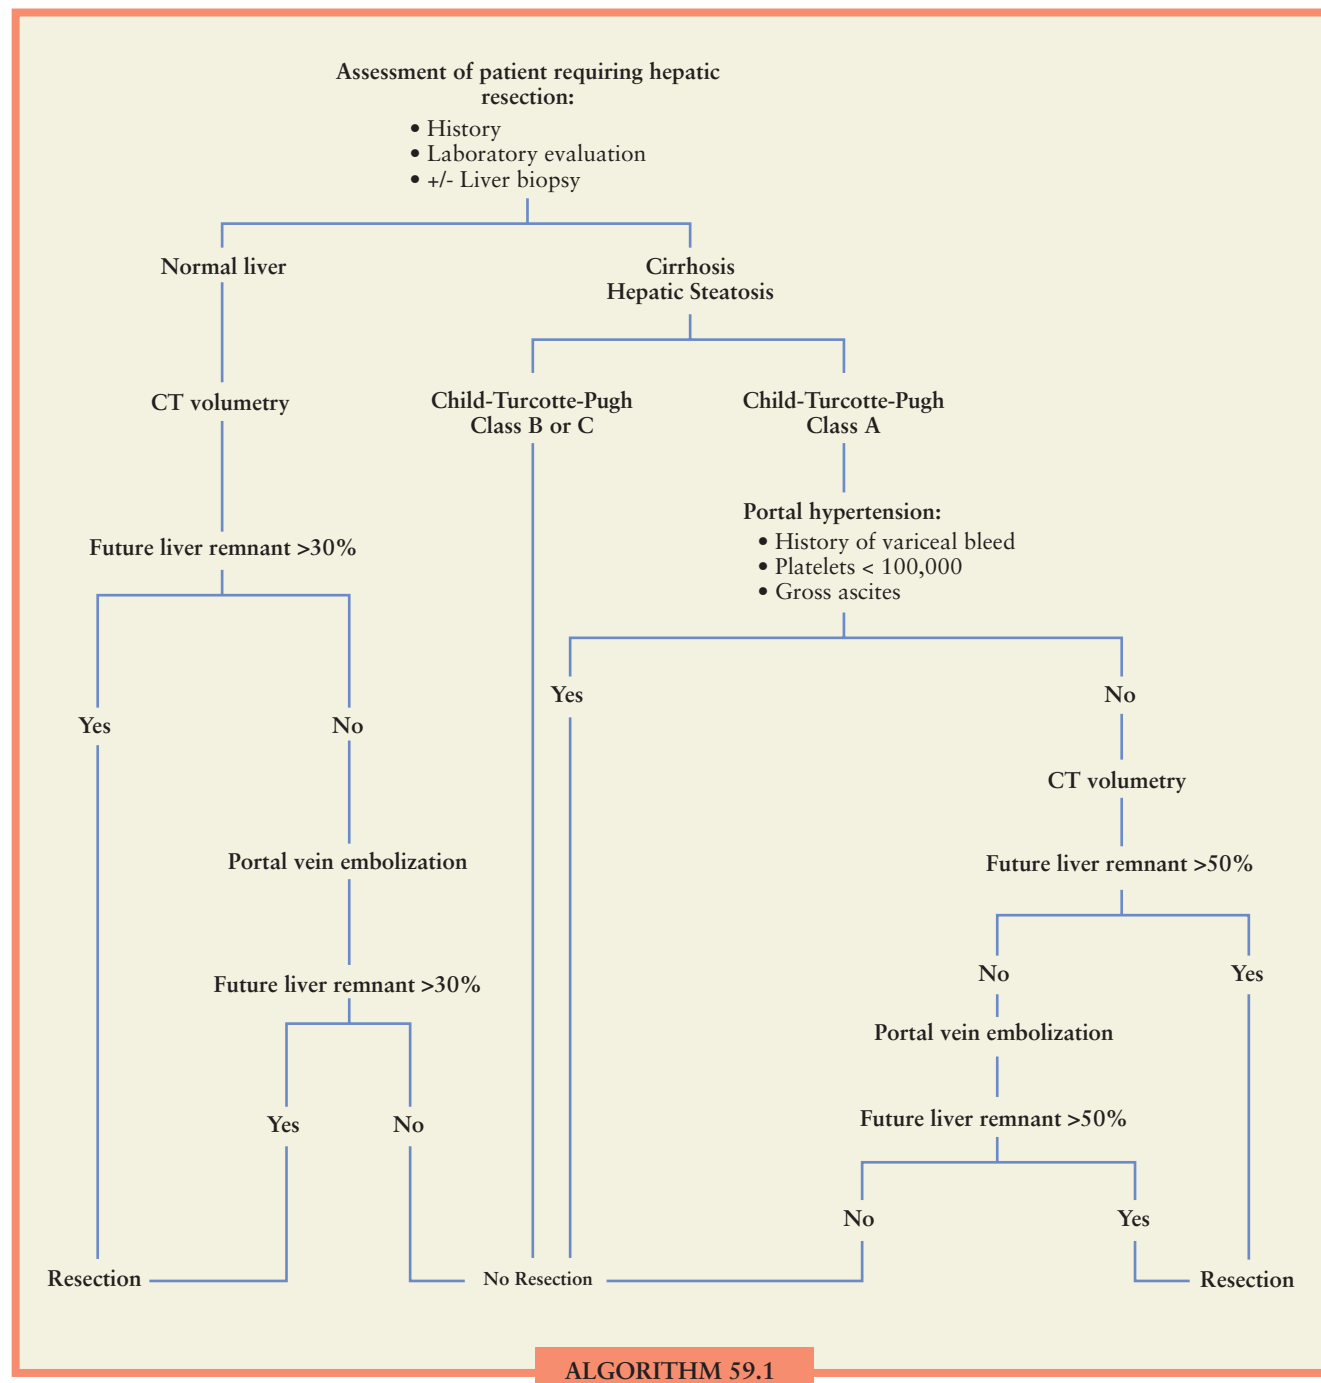

Assessment of cirrhotic patients for evidence of significant portal hypertension is believed by most hepatobiliary surgeons to be a critical step in risk stratification for hepatic resection. Patients with clinical signs of portal hypertension, such as a history of variceal hemorrhage, esophageal or gastric varices

TABLE 59.1

CLASSIFICATION

CHILD-TURCOTTE-PUGH (CTP) CLASSIFICATION OF CHRONIC LIVER DISEASE

CLINICAL CRITERIA	POINTS		
	1	2	3
Albumin (g/dL)	>3.5	2.8–3.5	<2.8
Bilirubin (mg/dL)	<2.0	2.0–3.0	>3.0
Prothrombin time			
Seconds	<4	4–6	>6
International normalized ratio (INR)	<1.7	1.7–2.3	>2.3
Ascites	None	Moderate (or suppressed by medication, not requiring regular paracentesis)	Severe (tense ascites, refractory to medication, or requiring regular paracentesis)
Encephalopathy	None	Grade I–II (or suppressed by medication)	Grade III–IV (or refractory to medication)
CTP class A	5–6 points		
CTP class B	7–9 points		
CTP class C	10–15 points		

ALGORITHM 59.1. Proposed algorithm for evaluation of hepatic reserve in the patient being considered for hepatic resection. (Adapted from Clavien PA, Petrowsky H, DeOliveria ML, et al. Strategies for safer liver surgery and partial liver transplantation. *New Engl J Med* 2007;356:1553.)

on upper endoscopy, visible upper abdominal varices on cross-sectional imaging, or grossly apparent ascites, are not considered viable candidates for hepatic resection. Some centers have advocated direct measurement of the hepatic venous pressure gradient by percutaneous venous access with hepatic manometry,^{15,16} although other surgeons have disputed the necessity of this study given the accuracy of clinical signs of portal hypertension and the relative invasiveness of the manometry procedure.⁹ Thrombocytopenia is another critical clinical indicator of surgical risk with hepatic resection, reflecting the hypersplenism of advanced cirrhosis and portal hypertension.¹⁷ A platelet count under 100,000 is considered a contraindication to major hepatectomy.

A number of quantitative liver function tests have been investigated to assess hepatic reserve prior to hepatic resection, including indocyanine green (ICG) clearance,¹⁸ galactose elimination capacity,¹⁹ and technetium-99m galactosyl human serum albumin scan,²⁰ among others. The ICG clearance study is the most commonly used internationally, though it is not commonly used or available in the United States. ICG retention at 15 minutes (ICGR-15) is believed to be the most accurate predictor of postoperative outcome among CTP class A patients, though this value may be affected by such factors as hepatic blood flow. Advocates of this method of risk stratification believe that an ICGR-15 under 14% is associated with acceptable outcomes following major hepatectomy, while an

ICGR-15 greater than 20% is a contraindication to such a resection.^{21,22} Patients with an intermediate ICGR-15 of 14% to 20% must be considered selectively, with careful attention to remnant liver volume.^{8,9}

Considerable attention has been paid in recent years to evaluation of remnant liver volume as a method to stratify risk of postoperative liver failure, and this method is the most common method of evaluating hepatic reserve among hepatobiliary centers in the United States.²³ This assessment relies on the use of computed tomography (CT) volumetry, produced by manual or automated serial measurement of cross-sectional liver volumes produced from a rapid-sequence, thin-section helical CT scan. The volume of the liver segments to be preserved following resection is then divided by the total estimated liver volume, producing a percentage of future liver remnant volume. In patients with normal liver parenchyma and function, a future liver remnant volume of 25% to 30% is considered adequate, especially if two contiguous Couinaud segments are preserved. In patients with chronic liver disease, cirrhosis, or documented hepatic steatosis, a future liver remnant volume of 40% to 50% is desired. In such patients, preoperative portal vein embolization, as discussed later in this chapter, should be considered if the liver remnant volume will not be adequate. Particular consideration should be given to patients undergoing major hepatectomy with no overt liver disease but prior exposure to prolonged chemotherapy, as this may be associated with the development of hepatic steatosis and adverse postoperative outcomes.²⁴ Compromise of hepatic venous return should be considered as equivalent to leaving a smaller liver remnant. For example, in the case of an extended right hepatectomy that leaves most of segment 4 intact but sacrifices the drainage of the middle hepatic vein, estimated future liver remnant volumes might be more accurate if they ignored the contribution of most of segment 4. Sacrifice of segmental vascular inflow, though collateralized in the liver parenchyma to some degree, should also be considered when determining the volume of future liver remnant.

Radiographic Evaluation and Imaging Techniques

Liver imaging is a rapidly evolving field, and the proliferation of new technologies affords the surgeon multiple modalities and techniques for defining the anatomy of a hepatic neoplasm. Familiarity with the technology available within one's community or hospital, as well as a close alliance with experienced radiologists, will aid in the selection of the imaging technique that best informs treatment decisions. While a comprehensive discussion of liver imaging techniques is beyond the scope of this text, some important principles about each of the primary modalities should be considered.

Ultrasound. Transcutaneous ultrasound is often the most accessible and least invasive diagnostic study available for evaluation of hepatic anatomy, and these characteristics make it particularly applicable to screening of high-risk populations for HCC.²⁵⁻²⁷ Ultrasound is often the initial diagnostic modality in the evaluation of symptomatic liver masses, and is typically followed by dedicated cross-sectional imaging. In addition, ultrasound has important applications as a guide to percutaneous biopsy of liver lesions and to assist in the performance of percutaneous ablation or injection techniques.

As ultrasound may be limited in its ability to precisely evaluate the relationship of hepatic lesions to key vascular structures, most surgeons are more comfortable planning resection based on cross-sectional imaging. Nevertheless, ultrasound can be particularly useful in assessing specific lesions and may aid in narrowing a radiographic differential diagnosis. Cystic lesions in particular are well imaged by ultrasound, and characteristic

lack of internal echoes and posterior acoustic enhancement (through-transmission) may be adequate to distinguish a simple cyst from other lesions that require more careful evaluation. Use of Doppler color imaging may also add to the exam, but is often not definitive in defining specific pathology. For example, clinicians may propose to use ultrasound with Doppler to identify the vascularity of a hemangioma. However, the Doppler signal in these lesions is often subtle as the flow in the tortuous vessels that make up these lesions is of low velocity. Metastatic lesions can often have a similar flow signal, thus making ultrasound with Doppler inadequate to diagnose hemangiomas definitively. Nevertheless, liver ultrasound in experienced hands can offer useful information about liver lesions and associated anatomy and can guide subsequent diagnostic testing.

Computed Tomography. CT is the dominant cross-sectional imaging technique in the developed world, and is often the source for initial recognition of incidental hepatic neoplasms, as well as an important diagnostic tool for hepatic lesions when ordered for cause (such as investigation of a finding on screening exam, or a follow-up exam in a patient with a known malignancy). While a dedicated liver CT can be the definitive study for much liver pathology, the quality of hepatic imaging varies significantly by technique and timing of contrast administration. A standard single-phase intravenous contrast CT may provide excellent images of hepatic lesions, but can underestimate the burden of disease based on slice thickness and the lack of a true arterial and delayed phase images. Numerous examples of standard CT techniques missing subtle lesions that could affect treatment decisions may be cited, especially in the case of metastatic disease or HCC in patients with chronic liver disease where multifocality is common. For that reason, careful attention must be paid to the ordering of dedicated liver imaging, and communication to radiology of the indication for imaging is essential.

As is true of magnetic resonance imaging (MRI), attention is often particularly paid to the behavior of identified lesions throughout the distinct contrast phases of a liver CT: arterial, portal venous, and systemic (hepatic) venous. Definitive diagnostic criteria for HCC may be achieved, as discussed later, avoiding the need for biopsy in the majority of patients.

Magnetic Resonance Imaging. MRI has become the definitive imaging study for liver tumors in many centers, demonstrating increased sensitivity and specificity to CT in comparison studies. Furthermore, the addition of magnetic resonance cholangiopancreatography (MRCP) to liver tumor studies in appropriate patients (e.g., cholangiocarcinoma) offers distinct advantage over the cross-sectional images of CT. Like CT, liver MRI is highly dependent on technique, with the difference between a critical and useless study often defined by timing of contrast administration, synchronization of imaging series with patient breath holding and movement, and proper reconstruction of distinct imaging series. Again, institutional experience and expertise often determine which cross-sectional imaging study is appropriate for treatment planning.

Positron Emission Tomography. Positron emission tomography (PET) may be a powerful adjunct to other liver imaging techniques in appropriately selected patients. PET is often best reserved for defining the nature of small indeterminate lesions, identifying multifocal disease, and characterizing liver metastases in the context of the presence or absence of extrahepatic disease. Given the strong background of glucose metabolism in the liver, more subtle lesions such as HCC, which may closely resemble normal liver parenchyma on a cellular level, are poorly identified on PET. In the case of metastatic colorectal cancer, PET has become established as an important addition to cross-sectional imaging in defining the extent of metastatic disease and aiding in treatment planning. PET, particularly when performed in combination with synchronized CT imaging, has been shown to alter treatment decisions by aiding in the detection of

subtle hepatic metastases not well visualized on standard cross-sectional imaging studies and by adding sensitivity in the detection of extrahepatic metastases.^{28,29}

BENIGN HEPATIC NEOPLASMS

Cystic Lesions

The increased use of cross-sectional imaging has led to a marked increase in the diagnosis of incidental hepatic masses and lesions. The distinction between solid and cystic lesions is important, as the vast majority of cystic lesions of the liver are benign in behavior. The majority of incidentally discovered cystic lesions of the liver are simple or congenital cysts, lesions that have no malignant potential and rarely become symptomatic. In some cases, a large or dominant simple cyst may become symptomatic as it stretches the adjacent liver capsule or compresses adjacent organs. These lesions are ideal for laparoscopic resection or marsupialization, a procedure that can be performed safely with excellent results and negligible recurrence in experienced hands (Fig. 59.4).³⁰ In the case of patients with polycystic liver disease (PCLD), an autosomal dominant disease with variable penetrance and presentation, a minority of patients will develop disabling cystic hepatomegaly. In these patients, a variety of percutaneous^{31,32} and surgical methods^{33,34} have been attempted to alleviate symptoms, with liver transplantation^{35,36} reserved for select few patients with refractory symptoms and/or associated superinfection or hepatic dysfunction. Surgical resection and marsupialization of dominant cysts in PCLD can have reasonable results in well-selected patients, though the risk of complications and recurrence is higher than in similar patients with simple hepatic cysts.³⁷

2 The majority of cystic lesions are asymptomatic, and treatment is only indicated for lesions where there is concern for malignancy, or malignant potential. While a variety of primary and secondary hepatic neoplasms can have cystic components or degeneration, biliary cystadenomas are the most important

FIGURE 59.4. Contrast-enhanced computed tomography of a large bilobed simple hepatic cyst in a 73-year-old female who presented with an abdominal mass and early satiety. The patient underwent laparoscopic resection of the anterior cyst wall with complete resolution of symptoms. Pathology of the cyst wall was consistent with a simple cyst.

primary cystic neoplasms of the liver, accounting for approximately 5% of all cystic lesions of the liver.³⁸ These neoplasms arise from the biliary epithelium, typically present in middle-aged women, and can vary markedly in size. Cystadenomas have a propensity toward local recurrence and malignant degeneration to cystadenocarcinoma.^{39,40} The diagnosis of cystadenoma can be made radiographically in select circumstances, as classic lesions will demonstrate internal septae with papillary projections.⁴¹ Intratumoral hemorrhage or fine calcifications may be present. Contrast enhancement on CT or MRI can suggest the presence of cystadenocarcinoma, though the definitive distinction between cystadenoma and cystadenocarcinoma without a surgical specimen is typically not possible. Cyst fluid analysis by percutaneous aspiration may aid in the diagnosis of cystadenoma versus simple cyst, as elevated fluid CA 19-9 and carcinoembryonic antigen (CEA) levels may be present in cystadenoma, but again cannot reliably distinguish benign from malignant disease.⁴² For this reason, surgical resection is recommended in all cases where biliary cystadenoma is suspected or cannot be definitively excluded.

Solid Lesions

Solid mass lesions of the liver deserve more careful consideration in regards to surgical therapy and follow-up imaging. Dedicated liver MRI or CT can make the definitive diagnosis of a benign solid lesion, obviating the need for serial imaging in asymptomatic patients. While there are many benign solid lesions of the liver, the vast majority of clinical decision making for benign hepatic lesions relates to the proper distinction between hemangioma, hepatic adenoma, and focal nodular hyperplasia (FNH). Each of these lesions will be discussed here.

Hemangioma. Hemangiomas of the liver, like their relatives in other anatomic locations, are congenital tumors of disorganized vasculature with intervening fibrous tissue of variable quantities. The tumors are composed of multiple intertwined vessels, the size of capillaries, but may contain larger vascular channels with cavernous transformation. The vast majority are small in size (approximately 80% will be <4 cm),⁴³ though enormous lesions (>10 to 20 cm) may be encountered. Approximately 10% to 20% of persons with hepatic hemangioma will have multiple lesions.^{43,44}

Hemangiomas represent the most common benign neoplasm of the liver, at least in clinical practice (subcentimeter biliary hamartomas are likely more prevalent). Autopsy studies suggest that hemangiomas are present in 4% to 20% of individuals.^{45,46} Most hemangiomas are identified in individuals ages 40 to 60, though this age at presentation will likely fall with the increased use of abdominal ultrasound and cross-sectional imaging for other indications in younger patients. Hemangiomas, like other benign hepatic neoplasms, appear to be more common in women, with a female-to-male ratio of at least 2:1.⁴³ The use of female sex hormones for oral contraception or hormone replacement therapy is associated with a slight increase in hemangioma size at presentation, and appears to be more likely associated with a solitary hemangioma rather than multiple lesions.⁴⁴ In addition, ongoing sex hormone exposure appears to be associated with an increased incidence of enlargement in some women with hepatic hemangioma.

The majority of hepatic hemangiomas present as asymptomatic, incidental findings found on imaging studies performed for other indications. These lesions are also commonly identified incidentally at the time of operative exploration for another diagnosis. While there are reports of spontaneous or traumatic hemangioma rupture in exceptional cases (~30 cases in the surgical literature), there are no clear risk factors to predict this extremely rare occurrence.⁴⁷ Thus, the vast majority of hepatic hemangiomas can be left undisturbed, with surgical therapy reserved for the symptomatic hemangioma. Surgical dogma has

FIGURE 59.5. Magnetic resonance imaging of a hepatic hemangioma, demonstrating hypointensity on unenhanced images (*upper left*) and peripheral nodular enhancement with centripetal progression of enhancement on contrast-enhanced images (*upper right, lower left, lower right*). No treatment was recommended for this asymptomatic incidentally discovered lesion.

suggested that hemangiomas over 10 cm in size should be considered for excision, though again there are no clear data to support this practice in asymptomatic lesions. Radiographic follow-up of larger asymptomatic hemangiomas is also probably unnecessary, as size at presentation does not appear to predict any risk for growth.⁴⁴ The only potentially effective intervention for asymptomatic hemangiomas in appropriate female patients would be to recommend cessation of hormonal therapy.

Accurate radiographic diagnosis of a hepatic hemangioma is essential, as establishment of this diagnosis requires no additional intervention or test in almost all patients. MRI is now considered the most sensitive and specific imaging modality for hemangioma. Hemangiomas have a homogeneous high signal on T2-weighted images and demonstrate a pathognomonic pattern of initial peripheral, nodular enhancement following intravenous gadolinium administration with progressive infilling of the lesion on delayed sequences (Fig. 59.5).^{48,49} Contrast-enhanced CT demonstrates a similar pattern of peripheral to central filling on delayed images. Ultrasound of hepatic hemangioma typically reveals a well-defined lobular lesion with increased echogenicity, though these characteristics may be less reliable in larger lesions. Historically, tagged red blood cell studies have been used to confirm the diagnosis of hemangioma, but this study is not necessary when the preferred high-quality MRI or CT is available. Biopsy, though not absolutely contraindicated when hemangioma is in the differential diagnosis,⁵⁰ should not be necessary with appropriate imaging.

Symptomatic hemangiomas of the liver may present with abdominal pain, evidence of intratumoral or intraperitoneal rupture, or Kasabach-Merritt syndrome (thrombocytopenia and consumptive coagulopathy associated with a massive cavernous hemangioma).⁵¹ Symptomatic lesions tend to be large

(>10 cm) and located on the periphery of the liver with stretching of the liver capsule that some surgeons believe accounts for the pain associated with these lesions. Care should be taken not to blame a small hemangioma for nonspecific abdominal pain; longitudinal studies seem to suggest that hemangioma under 5 cm are rarely, if ever, symptomatic.⁴³ Intratumoral hemorrhage noted on CT or MRI may also be associated with pain in some patients, and is a generally accepted indication for surgical excision. Significant ongoing hemorrhage is extremely rare, but case reports seem to indicate that an initial approach of hemodynamic stabilization, transcatheter intra-arterial embolization, and subsequent surgical excision is the preferred approach when resources are available.⁵²

Elective surgical treatment of a symptomatic hemangioma may be accomplished by either enucleation or formal hepatic resection. Enucleation is often surprisingly simple to accomplish, as most large symptomatic lesions are exophytic to some degree and a pseudocapsular plane can be developed efficiently. Incision into the Glisson capsule adjacent to the hemangioma allows identification of the proper plane, which is truly distinct from the hepatic parenchyma. Progression along the pseudocapsule of the lesion may be accomplished with hydrodissection, an ultrasonic dissector, or blunt dissection. Multiple small feeding vessels appear to be far more common than a single large inflow vessel, and these vessels may be methodically controlled with ligatures, bipolar cautery, or other surgical energy devices. Inflow occlusion with a Pringle maneuver may be helpful to decompress an exceptionally large hemangioma, but is often not necessary with an enucleation procedure. A formal anatomic or nonanatomic hepatectomy may be accomplished in cases where enucleation is more difficult, such as the rare symptomatic intraparenchymal lesion.

Techniques of hepatectomy described later in this chapter, including liberal use of intraoperative ultrasound, would apply. Excellent outcomes should be the standard in the surgical therapy of patients with hemangiomas.⁵³ Symptomatic lesions in poor surgical candidates can be treated effectively with focal external beam radiation or embolization.

Hepatic Adenoma. Hepatocellular adenomas are rare benign tumors of the liver, with an estimated prevalence of approximately 1% on postmortem exams.⁴⁵ The incidence of adenoma has appeared to increase notably with the more common use of oral contraceptives, an association made by the famed hepatobiliary pathologist Gerald Klatskin and others in the late 1970s.⁵⁴ There appears to be a directly proportional relationship between oral contraceptive exposure and adenoma risk, with a fivefold increase in incidence among women on oral contraceptives for more than 5 years.⁵⁵ Adenomas have also been associated with anabolic steroid use and glycogen storage disease, but may occur sporadically. Hepatic adenomatosis, originally defined as greater than 10 hepatic adenomas, appears to be a distinct entity from hepatic adenoma with different implications for treatment.⁵⁶ Germline mutations in hepatocyte nuclear factor 1 α may be associated with a subset of cases, with other genetic defects suspected in other forms of the disease.⁵⁷

Adenomas are well-circumscribed lesions that contain sheets of hepatocytes without intervening biliary ductules or portal tracts. The hepatocytes are laden with glycogen and lipid, which contributes to their imaging characteristics. Adenomas are well vascularized, fed by the hepatic arterial tree. Adenomas may vary widely in size, but most historical series seem to indicate a median size of 4 to 8 cm.⁵⁸⁻⁶¹ Unlike the other more common benign hepatic lesions of hemangioma and FNH, adenoma appears to have a low but consistent risk of either rupture or malignant degeneration (Fig. 59.6). Thus, surgical resection is typically recommended in otherwise appropriate candidates. In small lesions (<4 to 5 cm) in women on oral contraception, some experts have recommended withdrawal of oral contraception with subsequent imaging at 6 to 12 months to document regression.^{62,63} Tumors with regression in size may be observed if hormonal therapy can be avoided

FIGURE 59.6. Magnetic resonance imaging of a hepatic adenoma consuming much of segments II and III, with intratumoral hemorrhage. This image, taken in the arterial phase following gadolinium administration, shows marked tumor enhancement, with the hemorrhagic component of the mass appearing hypointense to the tumor and surrounding liver. The patient was a healthy 25-year-old female on oral contraceptive pills who presented with acute epigastric pain. The lesion was resected with a laparoscopic left lateral segmentectomy.

definitely. More recently, other surgeons have argued that the safety of hepatic resection, and the increasing use of minimally invasive hepatectomy, has lessened the risks and burdens of liver surgery such that all adenomas, and other lesions with any diagnostic uncertainty, should be resected.⁶⁴ While the risk of any hepatic surgical procedure should not be overly minimized, a strategy of surgical excision should be the default pathway in most patients with a diagnosis of hepatic adenoma.

With surgical excision the preferred approach for hepatocellular adenoma, the establishment of an accurate diagnosis for these lesions remains paramount. MRI provides the most definitive imaging study in the majority of patients. Adenomas are well-defined lesions with isointense or hyperintense (depending on the fat content of the lesion) features on T1- and T2-weighted images. With gadolinium administration, adenomas typically enhance markedly in a uniform manner on the arterial phase and disappear (become isointense) on the portal phase of imaging. CT imaging characteristics are similar, with a bright enhancement on the arterial phase of contrast administration. On ultrasound exam, adenomas are well circumscribed but have few other specific features to allow distinction from other hepatic neoplasms.

The distinction between adenoma and FNH can be difficult even with optimal cross-sectional imaging if the characteristic central scar and feeding artery of FNH are not visualized. Unfortunately, biopsy can sometimes be unreliable in this same diagnostic dilemma.⁶⁵ A 99m-technetium sulfur colloid scan can be considered in such cases, as an adenoma will not take up the radionuclide tracer due to the absence of Kupffer cells, while an FNH will typically demonstrate uptake. The failure to establish a definitive diagnosis of FNH is considered an indication for resection due to the risks associated with an undiagnosed adenoma. Patients with significant contraindications to surgical therapy should have oral contraception withdrawn and be enrolled in an annual surveillance program.

Focal Nodular Hyperplasia. FNH is often cited as the second most common benign neoplasm of the liver, after hemangioma. Clinical and autopsy series estimate that FNH occurs in 4% to 8% of individuals, with a strong predilection for women ages 20 to 50.^{45,66-68} However, recent evidence suggests that calling FNH a neoplasm is perhaps a misnomer. Wanless et al. first suggested that FNH is a hyperplastic response of normal hepatic parenchyma to localized areas of increased arterial perfusion, facilitated by the existence of small arteriovenous malformations.⁶⁹ To that end, FNH is known to be associated with vascular diseases associated with arterial hyperperfusion of the liver, including hereditary hemorrhagic telangiectasia or congenital absence of the portal vein.⁶⁹⁻⁷³

FNH appears as a firm mass that is often slightly lighter in color than the surrounding hepatic parenchyma. Importantly, it lacks a true capsule, a characteristic that distinguishes FNH from adenoma or hemangioma. FNHs are usually located in the periphery of the liver, in a subcapsular position, and may be quite pedunculated. Histologically, the lesions consist of normal hepatic elements but the hepatocytes are not organized in normal cords around the sinusoids. Proliferating bile ductules may be present, but do not connect to the biliary tree proper.⁶⁸ Fibrous septae of various degrees of organization and maturity may be present, as well as areas of necrosis. These features account for the central stellate scar that may be seen radiographically in a large proportion of these lesions.⁷⁴

The majority of FNHs are asymptomatic, found incidentally with abdominal imaging for other indications, or at laparoscopy. Peripheral or pedunculated lesions that grow to significant size (5 to 10 cm) may be associated with abdominal pain or fullness in rare cases. Unlike adenoma, the risk of rupture and hemorrhage is extremely rare, though a handful of cases have been reported in the medical literature.⁷⁵ FNH is also not a premalignant lesion; thus, treatment should be reserved for patients with persistent symptoms not explained by another problem.

FIGURE 59.7. Gadolinium-enhanced magnetic resonance imaging of the liver, revealing a mass consistent with focal nodular hyperplasia. Note the bright contrast enhancement on the arterial phase, with prominent central scar that appears hypointense on this early phase of imaging.

Diagnosis of FNH can be established radiographically with current modalities. On unenhanced CT, FNH may be well defined with mass effect on adjacent vascular structures. The lesions are typically isoattenuated with normal liver and may have the characteristic hypoattenuated central scar. With contrast in the arterial phase, FNHs enhance brightly and become again isoattenuated to adjacent parenchyma in the portal phase. Small feeding vessels may be seen on the periphery of these lesions in the arterial phase. The central scar may enhance on delayed phases.

Similar enhancement patterns may be seen on a liver mass protocol MRI with gadolinium administration. FNHs appear typically isointense on T1-weighted sequences, and T2-weighted images will often reveal hyperintensity of the central scar. The entire lesion will enhance brightly and uniformly following gadolinium administration in the arterial phase, while the central scar will become hyperintense on delayed phases (Fig. 59.7). The intense and homogenous arterial enhancement of FNH helps distinguish the lesion from other hepatic masses that enhance in the arterial phase and become isointense in more delayed phases (e.g., HCC).⁷⁴

Because of the typical indolent nature of FNH, its lack of malignant potential, and the characteristic radiographic features, the role of the surgeon in the management of this lesion is most often reduced to offering important reassurance to patients with incidental diagnoses. Indications for surgical resection should be limited to the rare patient with overt symptoms and the occasional case where the lack of classic imaging characteristics makes establishing a clear benign diagnosis difficult.⁷⁶ In the latter case, biopsy may also be confounding, as the normal cellular elements in FNH can make definitive diagnosis difficult, particularly if the fibrous scar elements are not sampled in the biopsy specimen.

PRIMARY HEPATIC MALIGNANCIES

Hepatocellular Carcinoma

HCC is the most common primary hepatic malignancy and is one of the most prevalent solid malignancies worldwide.⁷⁷ In the United States, its incidence is increasing the second fastest

of any other tumors, believed to be related primarily to the hepatitis C (HCV) epidemic.⁷⁸ Risk factors for HCC include all problems causing chronic hepatitis or cirrhosis. HCV ranks the highest in risk, with a 3.7% to 7.1% annual incidence of HCC, and hepatitis B infection comes in at a close second, with a 2.2% to 4.3% annual incidence of the malignancy.⁷⁹ Other risk factors include alcohol, cirrhosis of any cause, aflatoxin, androgenic hormones, hemochromatosis, α_1 -antitrypsin deficiency, glycogen storage diseases, hypercitrullinemia, porphyrias, hereditary tyrosinemia, Wilson disease, and any hepatic toxin exposure. Its incidence is certainly higher in areas of Asia and Africa where viral hepatitis or aflatoxin exposure is more endemic.

Screening for HCC has been examined in numerous trials, primarily focusing on the role of serum α -fetoprotein (AFP) determination and hepatic ultrasound.^{25–27} While some controversy still exists about the frequency of screening and relative cutoff values for AFP, the American Association for the Study of Liver Disease (AASLD) has made guidelines regarding the use of these screening techniques based on the best existing evidence.⁸⁰ The AASLD currently recommends serial hepatic ultrasound and serum AFP every 6 to 12 months in at-risk populations (e.g., any patient with cirrhosis). However, a recent Chinese study evaluating primarily hepatitis B patients showed that the use of ultrasound and AFP could lower HCC-related mortality by 37%.⁸¹ When a diagnosis of HCC is suspected, a contrast-enhanced three-phase MRI is more preferred than a CT in that there is an improved sensitivity and specificity of approximately 75% and 76%, respectively, compared to 61% and 66%, respectively, for CT.^{82–84} The characteristic features of HCC on MRI or CT include arterial enhancement with early washout of contrast on the delayed phases of the scan (Fig. 59.8). These enhancement characteristics increase the specificity of the scan to greater than 95%.⁸⁵ Biopsy is reserved for cases in which the diagnosis is still in doubt following adequate imaging or in cases where it is thought to change management based on clinical suspicion.

3 Once the diagnosis of HCC is established, the choice of therapy must be individualized to each patient and based on tumor burden, degree of underlying liver disease, patient performance status, and the overall possibility of side effects or complications balanced with acceptable results. The therapeutic goals must also be individualized to either palliative or curative. Overall survival represents the best standard by which to judge most therapies as this measure incorporates much of the aforementioned patient-related factors. Therefore, the Barcelona Clinic Liver Cancer (BCLC) staging system (Algorithm 59.2) is considered the most current method to adequately stratify patients for specific therapies and has now been independently validated as superior to other staging systems used in the past.^{86,87}

Resection is the treatment of choice for patients without liver disease; however, consideration of resection for cirrhotic patients requires greater scrutiny. Selection of patients for resection is critical and dependent on the following factors: degree of fibrosis, future liver remnant, patient performance status, tumor characteristics, and whether patients are similarly benefited by other therapies such as transplantation or radiofrequency ablation (RFA). In the best selected patients, survival rates at 5 years can vary from 38% to 70%, primarily depending on tumor stage.^{88–90} Indeed, Child class B patients can have 5-year survival rates following resection of 20% to 50%, which approaches the survival rates of ablative therapies for tumors of similar size.^{91–93} The perioperative mortality rate following resection for HCC is on the order of 4.0% to 4.7%, higher than mortality rates for benign disease or colorectal metastases,^{94,95} reflecting the burden of chronic liver disease among patients with HCC.⁹⁶ Aside from liver disease burden, the presence of tumor vascular invasion is the single most important predictor of outcome following resection, decreasing

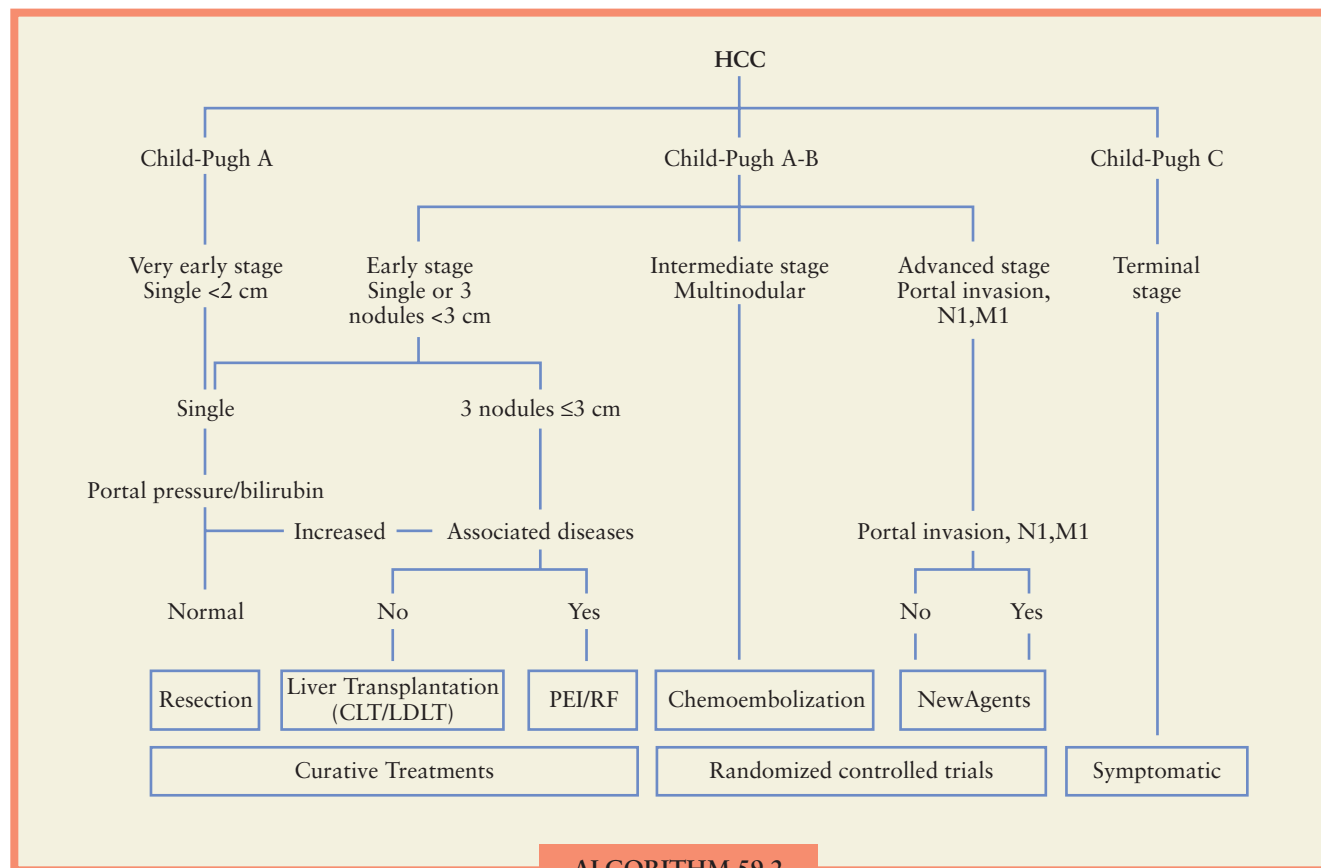

FIGURE 59.8. Magnetic resonance imaging of hepatocellular carcinoma, demonstrating characteristic enhancement on arterial phase imaging (left panel) with washout of contrast on delayed-phase imaging (right panel).

5-year survival from 41% to 57% to 15% to 34%.^{90,97} Whether tumor size or tumor number is independently associated with worse outcomes is more controversial, as both of these factors are thought to have higher associations with vascular invasion as well.⁹⁷ In concordance, patients with very

large HCCs, without vascular invasion or associated liver disease, can experience 5-year survival rates of 54% to 57.7% following resection.^{98,99} Currently, there is no known benefit for adjuvant therapy following resection for HCC other than therapies aimed at treating the presence of viral hepatitis for

ALGORITHM 59.2. Algorithm for staging and treatment of hepatocellular carcinoma (HCC) according to the Barcelona Clinic Liver Cancer staging system and published as the American Association for the Study of Liver Diseases Practice Guidelines for HCC. acceptable candidates.¹⁰⁰ Therefore, this represents an area of ongoing research, especially as newer medications arrive.¹⁰¹

4 Liver transplantation is a useful consideration for patients not otherwise candidates for liver resection due to cirrhosis and with early-stage HCC as defined by Mazzaferro et al.¹⁰² The staging definition set by these authors, now referred to as the Milan criteria, is defined as the absence of macrovascular invasion and a single tumor less than or equal to 5.0 cm or two to three tumors with none being greater than 3.0 cm. In the original study, patients experienced a 74% 4-year survival following liver transplantation. This survival rose to 85% when pathology on explant matched the preoperative imaging findings. Efforts to expand liver transplantation to patients with greater tumor burdens have met with mixed results and therefore more study is required before expanding this therapy to patients with greater stages of disease.^{103,104} However, downstaging patients just above Milan stage before transplantation with the use of RFA or transarterial chemoembolization (TACE) is gaining popularity, with a 2-year survival rate of 81% following transplantation for patients successfully downstaged.¹⁰⁵ Patients meeting the Milan criteria who are otherwise acceptable candidates for liver transplantation are generally awarded MELD exception points so as to minimize waitlist dropouts due to progression of tumor disease.

Several locoregional therapies have been developed for the treatment of HCC and include RFA, TACE, microwave ablation, percutaneous ethanol ablation,¹⁰⁶ cryotherapy, radiotherapy, and yttrium-90 microspheres. Of the ablative therapies, RFA has proven to be superior, with less recurrence and fewer treatment sessions required.¹⁰⁷ RFA appears to be most beneficial for tumors less than 4.0 cm in size having a survival rate of 74% at 4 years and efficacy increasing for even smaller tumors.^{108,109} Interestingly, a randomized controlled trial evaluating RFA versus resection for tumors less than 2.0 cm in size showed equivalent 4-year survival of 64% and 67.9%, respectively, and overall a decreased complication rate with RFA.¹¹⁰ However, more trials are clearly needed to evaluate outcomes for small HCCs.

TACE is a very useful therapy for patients not eligible for other regional therapies as it has been proven in several randomized trials to provide a significant survival advantage, increasing median survival from 16 to 20 months in a meta-analysis of these trials, and with one large study showing a median survival of 34 months.¹¹¹ TACE is performed using angiographic techniques followed by selective embolization of the hepatic arterial supply to the tumor often with the addition of doxorubicin and cisplatin.^{112,113} Relative contraindications to TACE include the presence of portal vein thrombosis or cirrhosis with many Child class B and all of Child class C patients being poor candidates due to risk of hepatic decompensation. Therefore, the best results are for patients with BCLC intermediate stage.^{80,111}

Experience is accumulating with yttrium-90 microspheres, introduced transarterially, with a large single center demonstrating a median survival of 12 months in treated patients with BCLC intermediate and advanced stage.¹¹⁴ External beam radiotherapy has also been used with one study showing a 75% tumor control rate at 2 years for large tumors not amenable to other treatments.¹¹⁵ Both of these therapies hold promise but will require further study.

The only known systemic medical therapy for HCC with proven efficacy is sorafenib, a multikinase inhibitor with activity against the vascular endothelial growth factor (VEGF) receptor 2, platelet-derived growth factor (PDGF) receptor, c-kit receptor, and kinases in the b-Raf/Ras/mitogen-activated protein kinase kinase (MAPKK) pathway. Sorafenib was studied in the phase III, placebo-controlled Sorafenib HCC Assessment Randomized Protocol (SHARP) trial.¹⁰¹ HCC patients not eligible for other therapies showed an increase in median survival with sorafenib therapy to 10.7 months when compared to placebo (7.9 months). Many other agents and compounds have been studied that have unfortunately shown no effect in randomized clinical trials. Other directed molecular

therapies that are currently under clinical trial include bevacizumab (VEGF inhibitor), erlotinib (endothelial growth factor [EGF] receptor inhibitor), sunitinib (multikinase inhibitor), and gefitinib (EGF receptor inhibitor).¹¹⁶

Intrahepatic Cholangiocarcinoma

Intrahepatic cholangiocarcinoma (CCA) is the second most common primary hepatic malignancy. Unlike extrahepatic cholangiocarcinoma, its development is thought to derive from a common hepatic progenitor cell that may also give rise to HCC.¹¹⁷ Indeed, some CCAs are characterized as a “mixed” histology with components of HCC and more classic CCA. Chronic liver disease or cirrhosis of varying etiologies is the only known risk factor for CCA, though many patients have no risk factors.¹¹⁸ The prognosis of CCA compared to HCC is clearly worse following therapy. Patients are more likely to present with an advanced stage of disease such as intrahepatic metastases or lymph node metastasis, both of which portend a very poor prognosis following surgical resection.^{119,120} Three-phase MRI and CT are the diagnostic modalities of choice, with biopsy being much more necessary as these lesions often appear hypointense on contrast-enhanced studies with no other clear primary gastrointestinal malignancies being noted. PET scanning is often helpful in contrast to extrahepatic CCA in evaluating for extrahepatic or intrahepatic metastases.^{121,122} Surgical resection is the only known effective therapy. Results are generally poorer than resection for most other hepatic malignancies as 5-year survival ranges from 25% to 43% for patients with an R0 resection and no lymph node involvement, depending on the presence of vascular invasion (25% to 31%) or intrahepatic metastases/satellite nodules (9.9% to 40%).^{119,120} The survival rate drops off dramatically for patients with positive lymph nodes, down to a 0% to 4% 5-year survival. Adjuvant therapy using radiation therapy or chemotherapy has shown no demonstrable benefit at the present time for this disease.

METASTATIC HEPATIC MALIGNANCIES

The management of metastatic disease confined to the liver is a rapidly evolving clinical challenge, particularly for metastatic colorectal cancer. As local and systemic therapies improve for various malignancies with a tendency to metastasize to the liver, the role of liver-directed therapy can in turn change considerably. In general terms, hepatic metastasectomy is best performed in two clinical scenarios:

- 5** 1. Isolated hepatic metastasis in select patients with established locoregional control of their primary disease and good overall oncologic prognostic indicators (such as long disease-free interval, solitary or few hepatic lesions, and response to systemic therapy). Metastatic colorectal cancer is the most common example of this type of disease.
2. Hepatic metastasis in cancers where additional treatment options for metastatic disease are limited, disease may follow a protracted and indolent course, and patient performance status is favorable. Metastatic neuroendocrine cancer is an example of this category of disease, though many cancer types may meet this definition in select cases.

Given this framework, hepatic resection for poor-prognosis cancers with synchronous or metachronous metastatic lesions may subject patients to notable surgical risk without offering the benefit of improved survival. Examples of cancers for which hepatic metastasectomy has had such a limited role include gastric, pancreatic, lung, and breast. As hepatic metastases are typically asymptomatic, palliative hepatic resection is rarely, if ever, indicated.

Given the extensive collective surgical experience that has been gathered in the treatment of metastatic colorectal cancer, much of the rest of this section will be dedicated to the discussion of that disease, though the oncologic principles could be applied to select patients with other malignancies.

Metastatic Colorectal Cancer

More than 145,000 Americans will be diagnosed with colorectal cancer annually, and up to 50% of patients will develop hepatic metastases at some time during their disease course.¹²³ Several important trends appear to have increased the number of patients with metastatic colorectal cancer to the liver who are eligible for surgical therapy: improved colonoscopy screening programs have increased the number of patients presenting with early-stage disease, posttreatment surveillance programs have identified developing metastatic disease earlier and more efficiently, and systemic chemotherapy has improved notably for colorectal cancer, extending the survival of patients with advanced disease such that more aggressive surgical treatment of metastatic disease has become more appropriate.

Diagnosis. There are multiple imaging modalities that can play a role in the diagnosis and treatment planning for hepatic metastases from colorectal cancer.¹²⁴ Diagnosis of metastatic colorectal cancer is typically made by abdominal CT scan, per-

formed either at the time of diagnosis or on surveillance imaging following treatment of a primary lesion. Hepatic metastases are slightly more common among patients with primary lesions in the rectum, and are clearly associated with regional lymph node disease. On standard single-phase intravenous contrast CT, hepatic metastases are typically more peripherally located low-attenuation lesions. Larger lesions may have central areas of necrosis or cystic degeneration. CT performed in three contrast phases (arterial, portal venous, systemic venous) may more sensitively identify subcentimeter lesions that are more difficult to identify in contrast to normal adjacent liver parenchyma. Hepatic metastases are often fed by the hepatic artery, and thus may enhance slightly on arterial phase, but remain less vascular than normal hepatic parenchyma. The lesions are of low attenuation in the portal phase. Mucin-containing lesions may have subtle calcifications. Contrast-enhanced liver MRI may offer additional sensitivity for small lesions and can be helpful in defining the extent of metastatic disease in patients with multiple small-volume lesions. Metastases typically have low signal intensity on T1-weighted images and high signal intensity on T2-weighted sequences. Contrast enhancement on MRI will give a similar appearance to metastases as with CT, with low signal intensity on unenhanced, arterial, and portal phases. PET has been advocated as an important study in the diagnosis of colorectal hepatic metastases and can play an important role in the evaluation for extrahepatic disease that may affect treatment decisions (Fig. 59.9). PET has

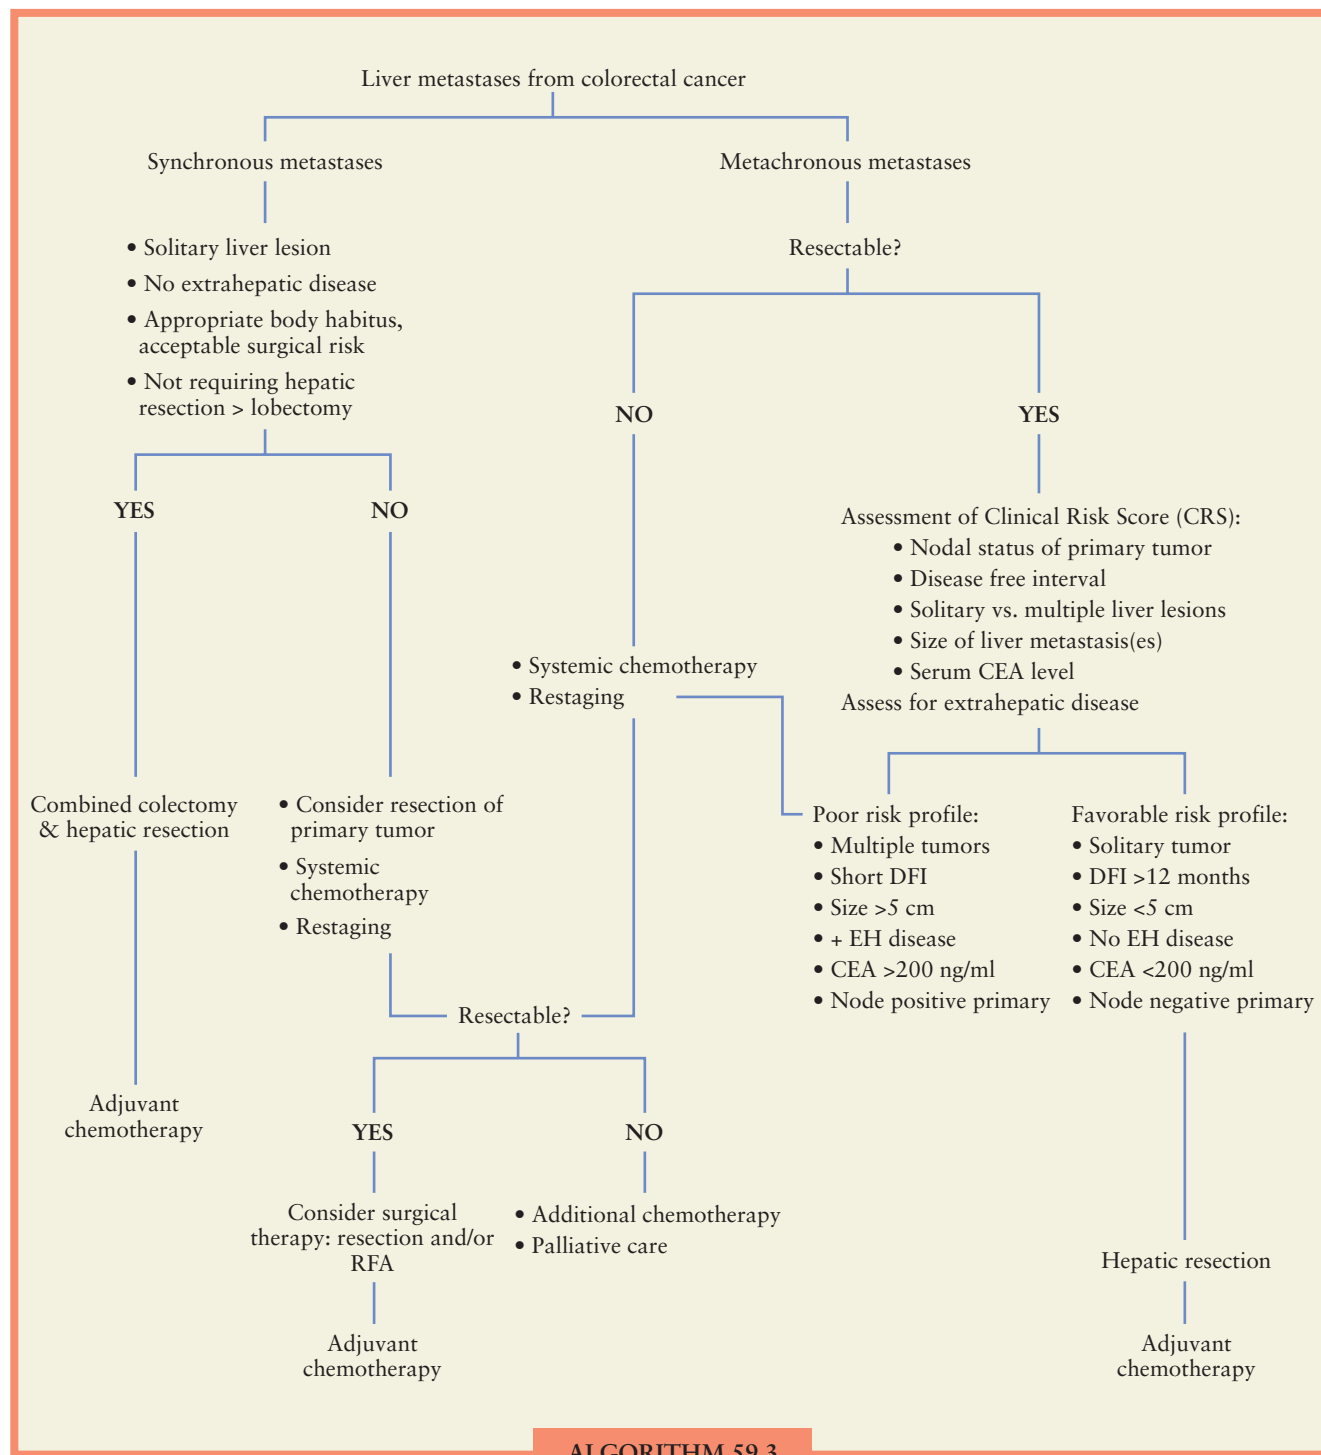

FIGURE 59.9. Positron emission tomography scan confirming hypermetabolic activity of lesions identified on corresponding computed tomography scans. *Black arrows* indicate hepatic metastases, and *white arrows* demonstrate portal and para-aortic lymph node metastases.

been demonstrated to change treatment decisions in up to 24% of cases when interpreted by experienced users.²⁸

In patients with known colorectal cancer, the development of new hepatic lesions with characteristic imaging findings is sufficient for diagnosis without biopsy. Biopsy may be helpful in patients without previous comparison imaging or equivocal lesions, or in patients with synchronous metastases without a tissue diagnosis. The tumor marker CEA may aid in the diagnosis of metastatic disease, but should be interpreted cautiously as 20% to 40% of patients with metastatic disease may have normal or minimally elevated serum CEA levels.^{125,126}

Treatment. Significant clinical experience in the surgical treatment of hepatic metastases from colorectal cancer has demonstrated the efficacy of hepatic resection (Algorithm 59.3). Multiple published series from high-volume centers have demonstrated 25% to 58% 5-year survival in select patients with surgically treated colorectal cancer metastatic to the liver (Table 59.2).^{95,127–137} Review of national Medicare data reveals 25% 5-year survival for patients treated with hepatic resection for colorectal metastases, an impressive durable survival for elderly patients treated at centers of variable experience.¹³⁸ Recent analysis of Surveillance, Epidemiology,

and End-Results (SEER)-Medicare data yielded similar good survival statistics in an unselected national population, revealing 33% 5-year survival with 30-day perioperative mortality of 4.3%.¹³⁹ Over the last two decades, the perioperative mortality associated with hepatic resection has fallen significantly, with less than 2% 30-day perioperative mortality regularly reported by high-volume centers,^{95,132,134,135} allowing the expansion of this therapy to more patients. The challenge to surgeons is to identify those patients most likely to benefit from hepatic resection, a population that is expanding with the influence of modern multidrug chemotherapy regimens. Considerable effort has been made to develop scoring systems that allow selection of patients most appropriate for hepatic resection.^{130,140-142} The clinical risk score (CRS) originally described by Fong et al.¹³⁰ and subsequently validated in independent patient populations,^{143,144} is the most widely used of these proposed prognostic indices. The presence of any of the following risk factors had a negative, and additive, effect on survival in patients with hepatic metastases from colorectal cancer: (a) node-positive primary tumor, (b) disease-free interval less than 12 months, (c) multiple liver metastases, (d) largest hepatic metastasis greater than 5 cm, and (e) serum

CEA level greater than 200 ng/mL. Patients with none of these risk factors may expect a 5-year survival of 60%, while there appear to be few long-term survivors among patients with all five risk factors (Table 59.3).

Synchronous Hepatic Metastases. The management of synchronous metastatic lesions has been a point of controversy in general surgery for decades. However, the improved safety of hepatic resection in recent years has made this a viable treatment strategy in appropriately selected patients.¹⁵³ Advantages of a single procedure include a single laparotomy and anesthetic experience, and earlier completion of surgical therapy such that adjuvant therapy can be initiated more quickly. A recent retrospective review from three high-volume centers suggests that simultaneous resection of the primary and hepatic disease, followed by adjuvant chemotherapy, provided improved survival when compared to staged resections with intervening chemotherapy.¹⁵⁴ Historically, patients thought to be appropriate for a combined procedure included patients who require a standard colectomy (e.g., right or left hemicolectomy). However, recent data demonstrate that patients requiring pelvic procedures for rectal tumors can undergo simultaneous hepatectomy

^aAdopted from Fong Y, Fortner J, Sun RL, et al. Clinical score for predicting recurrence after hepatic resection for metastatic colorectal cancer: analysis of 1,001 consecutive cases. *Ann Surg* 1999;230:309-318; discussion 318-321.

with acceptable outcomes.^{153,155} In contrast, the extent of the hepatectomy required can affect postoperative outcomes. Major hepatectomy (e.g., resection of at least three Couinaud segments) may best be handled in a staged fashion due to increased perioperative morbidity in patients undergoing simultaneous colorectal procedures.¹⁵³ Additional patient factors such as body habitus and comorbid disease should also influence surgical decision making in these cases.

Metachronous Hepatic Metastases. In metachronous metastatic disease, the appropriateness of hepatic resection may be dictated by patient comorbidity and prognostic indices such as the CRS.¹³⁰ The presence or absence of extrahepatic disease or local recurrence should be established with the use of cross-sectional imaging, PET, and colonoscopy. Presence of extrahepatic disease should influence treatment of hepatic metastases, as described later. In patients with good prognostic indicators (single small lesions, long disease-free interval), hepatic resection is most appropriate, followed by adjuvant chemotherapy. Patients with unresectable disease, or other poor prognostic indicators, should be considered for systemic chemotherapy, followed by restaging and consideration for surgical therapy.

Oligometastases. One particularly challenging group of patients with metastatic colorectal cancer include those with multiple hepatic metastases. If the patient otherwise has good risk factors and all the disease can be resected to a negative microscopic margin (R0), primary surgical therapy may be appropriate. Combination of radiofrequency ablation and resection in select patients may also be considered, though retrospective studies do appear to suggest that resection is superior to RFA when possible.^{133,156,157} Patients with oligometastases appear to be most appropriate for treatment with systemic chemotherapy prior to an attempt at surgical resection, similar to the principles that may be applied to patients with unresectable hepatic metastases as discussed later.^{158–161} This strategy provides several advantages, including the ability to observe the biology of the patient's cancer. Patients with progression of intrahepatic disease, or appearance of extrahepatic metastases, will exclude themselves from what is likely to be futile surgical therapy.¹⁵⁹ Response to chemotherapy appears to be an important prognostic factor for survival following hepatectomy.¹⁶² Additional advantages of preoperative chemotherapy include the ability to downsize metastatic lesions, making R0 resections more likely.

Strategies to Expand Application of Hepatic Metastectomy. As outcomes following metastasectomy for colorectal cancer have improved, strategies to expand the application of hepatic metastasectomy for colorectal cancer have continued to evolve. This evolution has been assisted by the improved efficacy of modern multidrug chemotherapy regimens, providing disease regression and stabilization that has facilitated progressive surgical approaches.

Unresectable Hepatic Metastases. In the case of patients with initially unresectable disease, either due to vascular involvement or the volume of liver parenchyma involved, neoadjuvant chemotherapy followed by reassessment of resectability has become common in experienced centers. Adam et al. reported a 12.5% resection rate among unresectable patients completing a multidrug regimen consisting typically of 5-fluorouracil/leucovorin and oxaliplatin (FOLFOX).¹⁶⁰ Despite the aggressive use of adjuvant surgical strategies including portal vein embolization (PVE), concomitant ablative procedures, and staged resections in 30% of patients, perioperative mortality was less than 1% with 33% 5-year survival, statistics that compare favorably to reported outcomes in more standard hepatic resection as described in Table 59.1. In a recent report by an Italian oncology cooperative, patients with unresectable hepatic colorectal metastases were treated with an aggressive regimen combining 5-fluorouracil/leucovorin, irinotecan, and oxaliplatin (FOLFOXIRI), which

facilitated a 19% R0 resection rate without perioperative mortality.¹⁶³ Median survival among patients undergoing R0 resection was 30 months versus 14 months in patients who were unable to undergo an attempt at surgical therapy due to lack of tumor regression. While further prospective study is required to optimize chemotherapy regimens and patient selection, it is clear that select patients with unresectable hepatic metastases from colorectal cancer can be treated with curative surgical intent.

Staged Hepatic Resection. In cases where the degree of hepatic parenchyma involved by metastatic colorectal cancer precludes a single definitive resection, staged hepatectomy can be performed with acceptable outcomes. This strategy takes advantage of the regenerative response of the liver following surgical resection, increasing the size of the liver remnant such that a second definitive procedure can be performed. A recent French report describes a strategy of initial systemic chemotherapy (typically FOLFOX), followed by the first hepatectomy, intervening chemotherapy delayed 3 to 4 weeks to allow initiation of liver regeneration, restaging, and second hepatectomy in patients where imaging suggests the possibility of an R0 resection.¹⁶⁴ Of the 59 patients initially treated, 41 (69%) completed the second hepatectomy, while the remainder developed progressive disease. Three deaths occurred due to liver failure following the second hepatectomy, though survivors of the two-stage approach achieved 42% 5-year survival. Smaller series have reported similar results, demonstrating the feasibility of this approach by experienced hepatobiliary surgeons.^{165,166}

Repeat Hepatic Resection. Patients with isolated hepatic recurrence following hepatectomy for metastatic colorectal cancer may be eligible for repeat resection in select cases. These procedures are typically more technically demanding, but published series suggest perioperative outcomes equivalent to primary hepatic resection.^{167–169} Oncologic outcomes, while inferior to primary hepatic resection, are acceptable, with 5-year survival rates of 26% to 35%.^{168,169} For these reasons, decisions about resection of recurrent hepatic disease should be made according to similar criteria as primary hepatic resection.

Treatment of Extrahepatic Metastatic Disease. Extrahepatic disease has traditionally been a contraindication to hepatic resection for metastatic colorectal cancer, and likely should remain so in the majority of patients. However, select patients with stable extrahepatic disease in addition to hepatic metastases may be appropriate for surgical therapy. Elias et al. reported a 29% 5-year survival among patients who underwent simultaneous resection of hepatic metastases and extrahepatic disease.¹⁷⁰ While published series have not been large enough to determine the prognostic significance of individual extrahepatic sites of disease, it appears that peritoneal metastases and multiple lesions portend worse survival. By far the greatest experience with extrahepatic metastasectomy for colorectal cancer exists for pulmonary resection, which can produce survival rates similar to hepatic metastasectomy in select patients.^{171–173} Similarly, perihepatic regional lymph node disease that stabilizes or regresses during chemotherapy can be resected at the time of hepatic resection with acceptable overall survival.¹⁷⁴ Lymphadenectomy for metastatic disease should be confined to the hepatic pedicle, as celiac and periaortic retroperitoneal metastatic lymph node disease appears to be associated with poor long-term survival.

SURGICAL TREATMENT OF HEPATIC NEOPLASMS

Hepatic Resection

- 6 Recent years have seen the expansion in the number of hepatic resections performed for multiple indications, a trend that is

associated with increased diagnosis of hepatic lesions due to better imaging, improved outcomes of patients with primary or secondary hepatic malignancies and an associated increase in the willingness to be aggressive surgically, and enhanced safety of these operations due to the evolution of advanced hepatobiliary techniques and perioperative management. Nevertheless, hepatic resection remains an operation associated with significant perioperative risk, and thus an increasing majority of these procedures are being performed by surgeons with advanced hepatobiliary and/or surgical oncology training. Recent reports from national administrative data suggest that overall mortality following hepatic resection is higher than that reported from high-volume experienced centers, emphasizing the impact of specialized care following this major operation.^{96,175,176}

Success in the operating room is created by careful preoperative planning. In addition to a standard medical evaluation, attention should be paid to factors that could make hepatectomy more complicated. Patients with significant hypervolemia (either due to renal or cardiac disease) or right heart failure with elevated central venous pressure (CVP) can pose particular challenges in liver surgery, as minimizing CVP has become a standard technique in liver surgery and is associated with decreased blood loss and improved outcomes.^{177,178} Previous abdominal surgery can make hepatic procedures more complicated, and should be planned for accordingly. Most importantly, assessment for underlying liver dysfunction is essential as previously discussed.

Portal Vein Embolization. Assessment of each liver resection patient for adequate hepatic reserve is critical to achieving good patient outcomes, as reviewed earlier and outlined in Algorithm 59.1. For the patient without an adequate predicted future liver remnant, PVE can be a necessary adjunct to expanding hepatic resection while avoiding postoperative liver failure. PVE takes advantage of the contralateral hypertrophy and ipsilateral atrophy that takes place in response to selective portal vein occlusion. Originally described in 1990, this technique has become a common procedure in high-volume hepatobiliary centers.¹⁷⁹ Portal vein ligation can be performed in an open or laparoscopic technique and can be used in staged hepatectomy procedures to induce hypertrophy prior to the second hepatectomy, but is most commonly performed via a percutaneous transhepatic approach. This allows access to lobar and segmental branches without manipulation of the portal supply to the future liver remnant. Repeat imaging is typically performed 3 to 4 weeks following embolization, with repeat liver volume estimates. Failure to respond to PVE portends a poor outcome following resection and should be considered a contraindication to proceeding with surgical therapy. Most centers will aim to operate on patients with an appropriate response at 21 to 30 days following PVE, capitalizing on the peak hypertrophic response at this time period. Published series report low rates of complications following PVE, with successful hypertrophy in the majority of patients.^{180–182}

Operative Technique. Perioperative management of the hepatic resection patient can have a profound influence on outcomes. A dedicated anesthesia team, with experience in advanced hepatobiliary procedures, can be associated with improved patient outcomes. Establishment of large-bore venous access is essential, and arterial line placement for systemic blood pressure monitoring is also advised. Central venous access, which has been advocated both for large-volume resuscitation and for CVP monitoring, can be helpful in the most complex cases, but is probably not necessary in limited resection cases. Use of large-bore peripheral intravenous catheters (14 or 16 gauge) and conservative volume resuscitation can achieve similar goals.

In the case of open hepatectomy, incision choice is critical to exposure and efficiency. Left-sided hepatic lesions can be

approached from an upper midline incision, but typically a right subcostal incision is preferred. A right subcostal incision with midline extension is a very versatile incision, allowing exposure to the suprahepatic vena cava, making a bilateral subcostal or Chevron incision necessary only for cases with difficult exposure due to body habitus or large tumors. In unusual cases with involvement of the suprahepatic vena cava or diaphragm, a median sternotomy or right thoracotomy extension may be necessary.¹⁸³ An appropriate retractor system, with bariatric blades for larger patients, can make a difficult case much easier.

As with all oncologic operations, the hepatectomy should begin with a thorough exploration of the abdomen, looking for extrahepatic disease that could change management of known intrahepatic disease. The liver should then be carefully inspected and palpated, with attention paid to any evidence of occult chronic liver disease or additional liver masses. Limited mobilization of the liver is then advisable prior to proceeding with the intraoperative ultrasound examination, as the exam is facilitated by mobilizing the liver such that the ultrasound probe has complete access to the hepatic parenchyma. However, if not necessary, leaving the ligamentous attachments of the future liver remnant intact can prevent torsion or compression of a small remnant. For example, in the case of a right trisegmentectomy, efforts should be made to preserve the left triangular ligament to keep the left lateral segment suspended in its typical anatomic relationship. In cases where it is necessary to take down such ligaments to facilitate exposure and mobility of the liver, the ligament can be reconstructed prior to abdominal closure.

Intraoperative ultrasound (IOUS) remains an irreplaceable tool in the surgical management of hepatic neoplasms, and has been shown to have increased sensitivity when compared to preoperative imaging.¹⁸⁴ Experienced hepatobiliary surgeons include the IOUS exam as a standard element of their operative exploration, typically following gross inspection and palpation of the abdomen and initial mobilization of the liver and placement of retractors. A careful IOUS should follow a reproducible and consistent three-step sequence, beginning with definition of the Couinaud segments based on the portal and hepatic venous anatomy. Attention is paid to important anatomic variants and anomalies, such as early or late division of the right portal pedicle or large accessory hepatic veins. The second phase of the IOUS exam should be a methodical scan through the entire liver parenchyma, with identification and measurement of all lesions. This is a critical step especially in operations where preoperative imaging identifies one dominant lesion; routine and thorough examination of the entire liver parenchyma is a crucial insurance against missing smaller synchronous lesions, which may be easily missed when distracted by a large known lesion. The whole liver scan should proceed in the same direction every time, typically in a cephalad to caudad position, moving slowly from the right to the left. Filling the upper abdomen with saline and removing any sponges from the field will prevent distracting echoes that can cause one to miss small peripherally based lesions. The final step in a comprehensive IOUS exam is planning of intended resection (or ablation), with note taken of the important critical vasculature to be included or avoided in a segmental resection. Mapping of the hepatic veins, for example, can be critical to avoid compromising venous drainage to the remnant liver in an extended resection.

The careful hepatobiliary surgeon will return to IOUS throughout the resection, ensuring that the resection margin is adequate and important vasculature is preserved. Caution often calls for temporary clamping of major portal branches, with subsequent Doppler IOUS confirmation of the intact flow to the liver remnant. A completion IOUS with Doppler to again demonstrate preserved inflow and outflow to the remnant liver should also be documented.

Once the plan of resection is confirmed by IOUS, the dissection phase is entered. The portion of the liver to be resected

FIGURE 59.10. Identification of the extrahepatic structures during portal dissection. A indicates the right main portal triad; B indicates the left main portal triad, with its longer extrahepatic segment. (Copyright © 2003, the University of Texas M.D. Anderson Cancer Center.)

should be mobilized completely, freed from diaphragmatic attachments with division of the hepatic suspensory ligaments. The portal structures should be isolated by opening the pars flaccida (gastrohepatic ligament) and passing a finger through the foramen of Winslow such that the porta can be encircled with a tape. This maneuver facilitates quick access to the porta

when necessary, and can facilitate episodic inflow occlusion. The amount of portal dissection necessary is then determined by the extent of hepatectomy planned (Fig. 59.10). A peripheral nonanatomic or segmental resection will not require much additional portal dissection. A formal or extended lobectomy may be approached with a formal portal dissection and pedicle control prior to parenchymal transection. Techniques of intrahepatic and extrahepatic pedicle control have been advocated by surgeons, depending on the tumor location and behavior.¹⁸⁵⁻¹⁸⁷ Extrahepatic ligation of the portal vein and hepatic artery on the side of the lobectomy is typically best for lesions close to the portal plate, and can be accomplished safely. Alternatively, dissection of the portal structures to allow segmental inflow occlusion with subsequent division of the inflow vessels in the parenchyma is a method to provide definitive vascular control without depriving the liver remnant of inflow during parenchymal transection (i.e., a selective Pringle maneuver). The only hazard of extrahepatic pedicle control or division is the risk of injuring portal structures to the remnant liver, especially the biliary drainage. For example, when performing a right hepatic lobectomy, care should be taken to divide the right hepatic duct at or above the level of the portal plate, as the left hepatic duct may have a high insertion that can be compromised when the right duct is ligated near the bifurcation.

Control of the hepatic veins is most commonly performed within the liver as the final step of parenchymal transection, but vascular staplers have provided an efficient way to control hepatic veins at their origin with even a small window of extrahepatic vein at the level of the caval insertion (Fig. 59.11). This is easiest for the right hepatic vein, but with caution and experience, the middle and left hepatic veins can be divided separately as well. Care should be taken not to narrow the vena

FIGURE 59.11. Exposure of the right hepatic vein for use of an endovascular stapler to ligate and divide the right hepatic vein. The liver is retracted medially and anteriorly after mobilization. (Copyright © 2003, the University of Texas M.D. Anderson Cancer Center.)

FIGURE 59.12. Parenchymal transection is carried out along the plane identified after vascular isolation. Parenchymal division can be performed by a number of different techniques, including coagulation dissecting devices or ultrasonic dissection. Large crossing ducts and vessels can be ligated with suture or clips, whereas smaller vessels are often readily coagulated with a variety of electro-surgical techniques. (Copyright © 2003, the University of Texas M.D. Anderson Cancer Center.)

cava or the hepatic veins that are being preserved during placement of a stapler or vascular clamp.

Parenchymal transection (Fig. 59.12) may be performed using multiple techniques (reviewed and discussed by Clavien¹⁸⁸), and the experienced surgeon can perform an efficient transection with minimal blood loss using the method with which he or she is the most proficient. The traditional clamp and crush technique, with control of small vessels using electrocautery, ligatures, and/or surgical clips, is relatively easy to perform and is likely the most efficient and cost-effective method for peripheral wedge resections in patients with normal liver parenchyma. Use of an ultrasonic or water-jet dissector is thought by many surgeons to provide the most precise plane of dissection, and can be essential for defining the anatomy and preserving critical structures with lesions located near the portal plate or hepatic veins. The harmonic scalpel or various bipolar cautery devices can control all but the largest parenchymal vessels, and may be used to speed up the transection phase. The use of vascular or gastrointestinal anastomosis (GIA) staplers has also become commonplace. These devices are best utilized in controlling major parenchymal branches such as the portal pedicle and hepatic veins, but some surgeons will divide the entire parenchyma with staplers once the line of transection is established and an appropriate margin is confirmed.^{189,190} One should note that the stapling devices work best when the liver capsule is not included, thus allowing the staples to compress and control the parenchymal vessels without getting caught on the capsule. Scoring the liver with electrocautery or the harmonic scalpel along the entire transection plane prior to firing the stapler will prevent this problem.

The role of inflow occlusion (Pringle maneuver) during parenchymal transection has been studied extensively and should be utilized to limit excessive blood loss when appropriate. While some surgeons use this technique routinely, others try to limit any potential ischemic injury to the liver remnant,

preferring selective pedicle isolation and ligation. When inflow occlusion is utilized, it appears that intermittent periods of clamping followed by periods of reperfusion can limit the ischemic injury to the liver remnant.¹⁹¹ The use of ischemic preconditioning, which has demonstrated value in animal models¹⁹² and some evidence of antiapoptotic effects in humans,¹⁹³ has not been shown in prospective studies to be clinically superior to intermittent portal clamping alone.^{194,195}

Once the parenchymal transection is completed, achieving final hemostasis is critical. Significant bleeding vessels should be controlled with nonabsorbable fine sutures or clips. The argon beam coagulator is effective for small vessels and raw surfaces. Application of additional hemostatic agents such as fibrin- and thrombin-based agents can also assist in achieving a dry operative field. Care should be taken to identify occult biliary leaks from the parenchymal surface, which should be controlled with fine sutures when identified. Leaving a surgical drain after a hepatectomy is a controversial practice¹⁹⁶ and appears to be only partially successful in allowing diagnosis and adequate drainage of a postoperative biliary leak. Selective use of drains for cases with concomitant biliary reconstruction and/or difficult perihilar dissection is probably a reasonable strategy.

Laparoscopic Liver Resection. The past decade has seen the rapid expansion of laparoscopic liver surgery, a technique that was first described in the early 1990s. Recent published series have documented that laparoscopic hepatic resection has similar benefits to other minimally invasive procedures when compared to open techniques, including less postoperative pain, earlier return to activity, and shorter length of stay.^{198–201}

8 Selection of patients appropriate for a laparoscopic approach to hepatic resection is critical, and should be performed with honest consideration of surgeon experience. Limited wedge resections and left lateral segmentectomies (segments II and III) are becoming standard laparoscopic procedures, with

a limited role for open hepatic resection in patients with these lesions. Major liver resections (lobectomy, trisegmentectomy, central hepatectomy, and resection of the posterior segments VI and VII) are complex laparoscopic procedures that should not be approached laparoscopically by surgeons without significant laparoscopic liver surgery experience. While tumors located near the hilum of the liver or with involvement of the vena cava and hepatic vein orifices have been addressed laparoscopically in highly experienced centers, these procedures should generally not be considered candidates for a minimally invasive approach. As technology and surgical experience evolves, it is likely that the majority of hepatic resection procedures will gradually become minimally invasive procedures, though this evolution should occur only with assurance of patient safety and oncologic outcomes equivalent to open techniques.

Evolution of Laparoscopic Hepatic Resection. Historically, laparoscopy was only used in liver surgery for the staging of tumors, biopsy of the liver, and treatment of simple cysts. In 1994, Croce et al. performed hepatic wedge resections in four patients utilizing argon beam coagulation.²⁰² One of these four patients developed cardiac arrest due to a gas embolism, hindering the enthusiasm for this technique. Six successful laparoscopic liver resections were reported in 1995 by Rau et al.²⁰³ The first anatomic liver resection was a left lateral segmentectomy performed by Azagra et al. in 1996.²⁰⁴ Kaneko et al. also reported laparoscopic left lateral segment resection during the same time period.²⁰⁵ Other attempts by groups with extensive open liver resection were less successful, with conversion rates to open resection in 6 of 11 patients (55%), suggesting a steep learning curve with this technique.²⁰⁶ Other early reports suggested a lower incidence of postoperative liver failure with laparoscopic approach (8% vs. 36%) along with improved 3-year survival (89% vs. 55%). While these findings were likely biased by patient selection, they did provide groundwork for the development of minimally invasive liver surgery.^{207,208}

Since that time, large studies have demonstrated the feasibility of laparoscopic hepatic resection and successful outcomes.^{209–211} In a comprehensive review of the literature, 75% of laparoscopic liver resections reported were performed totally laparoscopically and 17% were hand assisted. Conversion from laparoscopic to open occurred in 4% of patients. While wedge resections or segmentectomies were most common, formal right or left hepatectomies accounted for 16% of all cases reported.²¹¹ However, prospective studies comparing a minimally invasive to an open approach have not been performed and will be difficult to plan because of the technically demanding nature of this technique, which is selectively performed at specialized centers.

Limitations of Laparoscopic Liver Surgery. The performance of laparoscopic liver surgery requires experience and expertise in both open complex liver surgery and advanced laparoscopy. Minimally invasive surgery on the liver faces unique challenges including retraction and mobilization of a relatively large and heavy organ, limiting hemorrhage while performing parenchymal transection, and identifying intrahepatic anatomy or pathology without anatomic markers on the surface of the liver. Methods must be immediately available to control hemorrhage, including the ability for laparoscopic suturing, stapling techniques, inflow occlusion, the use of hand-assisted laparoscopy, or the conversion to open surgery. In addition, techniques to limit the risk of air embolism under pneumoperitoneum should be utilized. Central lesions and bulky tumors that compromise laparoscopic working space may be difficult to resect laparoscopically.

The laparoscopic resection of liver malignancies remains controversial, and arguments for and against are similar to those of other gastrointestinal malignancies.^{212,213} These arguments include concern for potential tumor cell exfoliation as well as port site metastases. In addition, concern for obtaining an inad-

equate margin has also been expressed. In a retrospective study that included 11 European centers, it was noted that almost one out of three patients did not meet a goal of a 1-cm margin on the specimen.²¹⁴ A more recent study has suggested that similar margins, recurrence rates, and long-term survival can be achieved in patients with malignant tumors using a laparoscopic approach when compared to open surgery.

These limitations and the constraints inherent in the utilization of evolving surgical devices should lead to the cautious adoption of laparoscopic liver resection, with laparoscopic major hepatectomy only performed by experienced surgeons. However, consensus appears to exist in the surgical community that laparoscopic approaches to liver surgery can produce equivalent outcomes to open hepatic surgery with appropriate patient selection and meticulous surgical technique.^{215,216}

Hepatic Resection with Vascular Isolation, Resection, and/or Reconstruction. Improved outcomes with hepatic resection, advances with anesthetic and critical care management of the hepatectomy patient, and the increasing influence of hepatobiliary surgeons with liver transplant experience have all contributed to the extension of hepatic resection to include treatment of malignancies that were previously considered either impossible or unsafe to resect. This includes hepatic tumors involving the vena cava and/or hepatic vein orifices, neoplasms associated with the portal vein or its major branches, and retrohepatic neoplasms involving or displacing the hepatic vasculature such as retroperitoneal sarcomas. Select expert hepatobiliary centers have demonstrated that patients with tumors in these unfortunate locations can be offered resection as long as such procedures adhere to the principles of patient selection, evaluation of hepatic reserve, and comprehensive oncologic care that are applied to patients with more typical hepatic neoplasms.

Initial forays into isolation of the hepatic inflow and outflow to facilitate the resection of centrally based and/or large hepatic tumors were first described in the 1960s,²¹⁷ and the technique of TVE should be familiar to all surgeons performing major hepatectomy (Fig. 59.13).²¹⁸ Bismuth et al. described the largest

FIGURE 59.13. The technique of total vascular exclusion (TVE) can facilitate the safe resection of a large and centrally based tumor, particularly when the vena cava or hepatic veins are involved.

initial series utilizing this technique, demonstrating no increased rate of complications beyond major hepatectomy without TVE.²¹⁸ Increasing comfort with this technique has led some surgeons to suggest its use for all major hepatic resection procedures, though recent systematic reviews of the available published studies showed no benefit of routine TVE over intermittent hepatic inflow occlusion.^{219,220} Nevertheless, TVE can be a lifesaving procedure in cases of massive hepatic hemorrhage, and may be necessary to allow the resection of tumors that involve or efface the vena cava or hepatic veins.

Recognition of the potential deleterious effects of the period of warm ischemia associated with TVE, which may be particularly injurious to steatotic or fibrotic livers,¹⁹⁷ led to interest in providing hypothermic perfusion of the liver during extended periods of TVE required for vascular resection and reconstruction. Azoulay et al. described the use of in situ hypothermic perfusion, demonstrating favorable results with no mortality in 20 patients.²²¹ The authors recommended consideration of hypothermic perfusion, either using in situ or ex vivo techniques, when TVE of more than 60 minutes would be required. Subsequent reports using this technique have described reconstruction of portal venous inflow to remnant liver segments,^{222,223} resection and reconstruction of the vena cava and hepatic venous drainage for hepatic neoplasms,²²⁴ and temporary total hepatectomy to facilitate resection and reconstruction of the vena cava for retroperitoneal tumors.²²⁵ While these procedures should be reserved for only experienced hepatobiliary surgeons, it is clear that they can be considered safe in select patients.

Liver Transplantation

Total hepatectomy and replacement with a liver allograft has been considered as a treatment for hepatic tumors since the earliest days of liver transplantation.²²⁶ Recognition of the profound impact that immunosuppression can have on tumor recurrence led to the conclusion that hepatic malignancy is a contraindication to liver transplantation. Experience with select tumors in rare circumstances, such as hepatoblastoma in children²²⁷ and the recent international experience with liver transplantation for early-stage HCC,¹⁰² has led to cautious optimism about the use of liver transplantation for malignancy. Currently, only HCC meeting Milan criteria in a patient with cirrhosis is considered a standard indication for liver transplantation (Table 59.4). Patients with other rare primary liver tumors such as angiosarcoma and epithelioid hemangioendothelioma can be considered for transplantation when resection is not an option. There is ongoing study about the

role of liver transplantation in the treatment of hilar cholangiocarcinoma²²⁸ and metastatic neuroendocrine tumors isolated to the liver.²²⁹ To date, there is little evidence to support extension of liver transplantation to other more common hepatic malignancies, such as metastatic colorectal cancer.

Ablation of Liver Tumors

Ablative techniques have evolved extensively over the past few decades, extending surgical therapies to small tumors in patients not appropriate for surgical resection. Many of these techniques can increasingly be performed percutaneously, but surgical approaches remain important in patients where transcutaneous approaches are not possible or when ablation is combined with resection in the case of multiple hepatic tumors. Available ablation techniques include cryotherapy, microwave coagulation therapy, and laser-induced hyperthermic ablation. By far the greatest international experience exists with RFA.

RFA involves the application of a high-frequency alternating current from the tip of an electrode to the tissue surrounding that electrode. As the ions within the tissue move in response to this current, frictional heat is generated. As the temperature in the tissue increases above 60°C, cells begin to die, ultimately leading to coagulative necrosis.²³⁰ Generally, ultrasound is used to guide the placement of the needle and ensure a complete therapeutic field. Once placed, RF energy is then applied across the needle electrode using an established protocol specific for the instrument (Figs. 59.14 and 59.15).²³¹ Smaller tumors can often be treated with one application, whereas larger tumors (>2.5 cm) will require more than one deployment of the electrode to ensure complete destruction of the lesion. Overlapping zones of coagulative necrosis are a key element in the use of RF ablative techniques requiring more than one deployment. To mimic a surgical margin of resectability, the electrode array is positioned so as to obtain a field of thermal necrosis including, when possible, a 1-cm perimeter of normal hepatic parenchyma surrounding each ablated lesion. After RF ablation, CT scans demonstrate cystic areas ideally larger than the original tumors. These ablation zones decrease in size over time.

Candidates for RF ablation of hepatic tumors are generally patients who do not meet criteria for resection of their disease but do not have evidence of extrahepatic disease.^{231,232} In selected cases, patients with tumors that are usually associated with disseminated, systemic metastatic disease (e.g., breast or renal cell carcinoma) may be considered for RF ablation if they have received a prolonged period of effective chemotherapy

and have evidence of metastases isolated to the liver. This group of patients is small, and only a few will derive long-term benefit from aggressive liver-directed interventions.²³³ As a result, RF ablation should be used only in patients with no preoperative or intraoperative evidence of extrahepatic disease and only for tumors with a reasonable probability of metastases restricted to the liver. Because some patients with metastatic neuroendocrine tumors can live for years with their disease, the only exception to this rule is in patients with functional endocrine syndromes from these types of tumors, minimal extrahepatic disease, and treatable liver metastases. In addition to treating multiple bilobar tumors that are unresectable because of distribution, RF ablation can also be used to address tumors in areas of anatomic constraint, such as a tumor juxtaposed to the confluence of the hepatic veins and inferior vena cava. The only area precluding RF ablation is the hilar plate because, although the portal vein and hepatic arteries tolerate heat, the bile ducts traveling with them do not and biliary fistulas or strictures are potential complications of thermal injury.

Radiofrequency ablation can be approached percutaneously with the assistance of ultrasound or CT guidance. A percutaneous approach does offer some advantages including being less invasive and in some cases not requiring general anesthesia. Elias et al. have reported that up to 16% of patients with extrahepatic disease may not be identified and up to 30% of additional liver lesions may be missed.²³⁴ In addition, radiofrequency ablation can be performed during open resection. With a laparoscopic approach, however, the benefits of minimally invasive surgery are realized along with the advantages of direct inspection and visualization of the liver and the opportunity to perform intraoperative ultrasound. With the assistance of laparoscopy, most lesions are accessible. Lesions near other structures, such as the colon or stomach, can be retracted and radiofrequency ablation can be performed safely without injury to surrounding organs. In addition, when near major vascular structures, vascular inflow occlusion can also be used to prevent a heat-sink effect. Disadvantages of the laparoscopic radiofrequency ablation approach include the requirement for general anesthesia and difficulty if extensive prior abdominal surgery has been performed. RFA can be combined with resection in select patients, allowing extension of surgical therapy to patients who otherwise would not have disease amenable to treatment of all visible tumor.^{133,156}

SUMMARY

The effective treatment of the patient with a hepatic neoplasm requires a comprehensive understanding of the diverse clinical presentations, pathology, and treatment options for benign and malignant liver tumors. A careful assessment of the patient's hepatic reserve, the precise anatomic details of the tumor location, and the oncologic context are necessary to choose the most effective course of therapy. Advances in surgical technique, perioperative management, and adjunctive therapies have extended the indications for hepatic resection for benign and malignant disease. Surgical therapy (resection, transplantation, ablation) remains the primary and most effective treatment for hepatic neoplasms, and excellent clinical outcomes should be expected in experienced hands even for these formidable procedures. Ongoing work is needed to appropriately extend surgical therapies to patients with advanced hepatic neoplasms, and to continue to develop adjuvant therapies that aid operative treatments in achieving improved patient outcomes.

CHAPTER 60 ■ CALCULOUS BILIARY DISEASE

HENRY A. PITT, STEVEN A. AHRENDT, AND ATTILA NAKEEB

KEY POINTS

- 1 Gallstones are classified by their cholesterol content as either cholesterol (70% to 80%) or pigment (20% to 30%), with pigment stones further classified as black or brown.
- 2 Biliary sludge refers to a mixture of cholesterol crystals, calcium bilirubinate granules, and a mucin gel matrix and is thought to serve as the nidus for gallstone growth.
- 3 The pathogenesis of cholesterol gallstones is clearly multifactorial but essentially involves four factors: (a) cholesterol supersaturation in bile, (b) crystal nucleation, (c) gallbladder dysmotility, and (d) gallbladder absorption/secretion.
- 4 Prophylactic cholecystectomy is generally not indicated in patients with asymptomatic gallstones, because studies show that only 20% to 30% will become symptomatic within 20 years and only 1% to 2% will develop serious complications per year.
- 5 Elective laparoscopic cholecystectomy is associated with a mortality rate of less than 0.3% and an overall complication rate of 10%, with less than 5% of patients requiring conversion to an open procedure.
- 6 Randomized trials have shown that early laparoscopic cholecystectomy performed for acute cholecystitis can result in a lower morbidity rate, shorter hospital stay, and quicker return to work than delayed cholecystectomy.
- 7 Chronic acalculous cholecystitis is associated with typical symptoms of biliary colic without evidence of gallstones and is diagnosed by cholescintigraphy with an ejection fraction of less than 35% in response to cholecystokinin.
- 8 Acute cholangitis results from the combination of significant bacterial concentration in bile and increased biliary pressure associated with biliary obstruction.
- 9 The strongest clinical indications for the presence of a common bile duct stone include a history of cholangitis, common bile duct stones identified on ultrasound, and jaundice; a patient with any one of these indicators has at least a 10 times increased risk of common bile duct stones.
- 10 Endoscopic cholangiography is the “gold standard” for the diagnosis of common bile duct stones, being successful in 90% to 95% of patients although associated with complications of cholangitis or pancreatitis in up to 5% of patients.

Calculous biliary disease is a major health care problem in developed countries as well as in many underdeveloped countries. In the United States, approximately 12% of the population or more than 30,000 Americans have gallstones. Currently more than 750,000 cholecystectomies are performed annually in the United States, and the cost of caring for these patients is estimated to be between \$7 million and \$10 million per year.¹ To properly manage these patients, surgeons should understand biliary physiology and gallstone pathogenesis, incidence, risk factors, and natural history as reviewed in the following discussion. In addition, this chapter reviews the diagnostic options, clinical manifestations, management options, and expected outcomes for calculous biliary disease.

BILIARY PHYSIOLOGY

Bile Flow

The bile ducts, gallbladder, and sphincter of Oddi act in concert to modify, store, and regulate the flow of bile. Approximately 600 to 750 mL of bile is produced daily. During its passage through the bile ductules, canalicular bile is modified by the absorption and secretion of electrolytes and water. The gastrointestinal hormone secretin increases bile flow primarily by increasing the active secretion of chloride-rich fluid by the bile ducts. Bile ductular secretion is also stimulated by other hormones such as cholecystokinin and gastrin. The bile duct epithelium is also capable of water and electrolyte absorption, which may be of primary importance in the storage of bile during fasting in patients who have previously undergone cholecystectomy. The main functions of the gallbladder are to concentrate and store hepatic bile during the fasting state and

deliver bile into the duodenum in response to a meal. The usual capacity of the human gallbladder is approximately 40 to 50 mL. Only a small fraction of the 600 to 750 mL of bile produced each day would be stored were it not for its remarkable absorptive capacity. The gallbladder mucosa has the greatest absorptive capacity per unit of any structure in the body.

Bile Composition

Bile is usually concentrated 5- to 10-fold by the absorption of water and electrolytes, leading to a marked change in bile composition (Table 60.1). Active sodium chloride transport by the gallbladder epithelium is the driving force for the concentration of bile.² Water is passively absorbed in response to the osmotic force generated by solute absorption. The concentration of bile may affect the solubilities of two important components of gallstones, cholesterol and calcium. Although the gallbladder mucosa does absorb calcium, this process is not nearly as efficient as the absorption of sodium or water, leading to a greater relative increase in calcium concentration. As the gallbladder bile becomes concentrated, several changes occur in the capacity of bile to solubilize cholesterol. The solubility in the micellar fraction is increased, but the stability of phospholipid-cholesterol vesicles is greatly decreased. Because cholesterol crystal precipitation occurs preferentially by vesicular rather than micellar mechanisms, the net effect of concentrating bile is an increased tendency to form cholesterol crystals.

Bile facilitates the intestinal absorption of lipids and fat-soluble vitamins and represents the route of excretion for certain organic solids such as bilirubin and cholesterol. The major organic solutes in bile are bilirubin, bile salts, phospholipids,

TABLE 60.1**COMPOSITION OF HEPATIC AND GALLBLADDER BILE**

■ CHARACTERISTIC	■ HEPATIC	■ GALLBLADDER
Sodium (mEq/L)	160	270
Potassium (mEq/L)	5	10
Chloride (mEq/L)	90	15
Bicarbonate (mEq/L)	45	10
Calcium (mEq/L)	4	25
Magnesium (mEq/L)	2	—
Bilirubin (mEq/L)	1.5	15
Protein (mEq/L)	150	—
Bile acids (mEq/L)	50	150
Phospholipids (mEq/L)	8	40
Cholesterol (mEq/L)	4	18
Total solids (mEq/L)	—	125
pH	7.8	7.2

and cholesterol. Bilirubin is the breakdown product of spent red blood cells and is conjugated with glucuronic acid prior to being excreted. Bile salts solubilize lipids and facilitate their absorption. Phospholipids are synthesized in the liver in conjunction with bile salt synthesis. The final major solute of bile is cholesterol, which is also produced primarily by the liver with little contribution from dietary sources. Cholesterol is highly nonpolar and insoluble in water and thus in bile as well.

Gallbladder Function

As a result of active absorption, the gallbladder stores concentrated bile that reenters the distal bile duct and is secreted into the duodenum in response to a meal. In addition to absorption and concentration, the gallbladder's mucosa actively secretes glycoproteins and hydrogen ions. Secretion of mucous glycoproteins occurs primarily from the glands of the gallbladder neck and cystic duct. The resultant mucin gel is believed to constitute an important part of the unstirred layer (diffusion-resistant barrier) that separates the gallbladder cell membrane from the luminal bile. This mucous barrier may be very important in protecting the gallbladder epithelium from the strong detergent effect of the highly concentrated bile salts found in the gallbladder. However, considerable evidence also suggests that mucin glycoproteins play a role as a pronucleating agent for cholesterol crystallization. The transport of hydrogen ions by the gallbladder epithelium leads to a decrease in bile pH through a sodium-exchange mechanism. Acidification of bile in the gallbladder promotes calcium solubility, thereby preventing its precipitation as calcium salts. The gallbladder's normal acidification process lowers the pH of entering hepatic bile from 7.5 to 7.8 down to 7.1 to 7.3.²

Biliary Motility

Gallbladder. Gallbladder filling is facilitated by tonic contraction of the ampullary sphincter, which maintains a constant pressure in the common bile duct (CBD) (10 to 15 mm Hg). However, the gallbladder does not simply fill passively and continuously during fasting. Rather, periods of filling are punctuated by brief periods of partial emptying (10% to 15% of its volume) of concentrated gallbladder bile. Emptying periods are coordinated with each passage through the duodenum

of phase III of the migrating myoelectric complex (MMC). This process is mediated, at least in part, by the hormone motilin. Following a meal, the release of stored bile from the gallbladder requires a coordinated motor response of gallbladder contraction and sphincter of Oddi relaxation. One of the main stimuli to gallbladder emptying is the hormone cholecystokinin, which is released from the duodenal mucosa in response to a meal. When stimulated by eating, the gallbladder empties 50% to 70% of its contents within 30 to 40 minutes. Gallbladder refilling then occurs gradually over the next 60 to 90 minutes. Many other hormonal and neural pathways are also necessary for the coordinated action of the gallbladder and sphincter of Oddi. Defects in gallbladder motility, which increase the residence time of bile in the gallbladder, play a central role in the pathogenesis of gallstones.³

Sphincter of Oddi

The human sphincter of Oddi is a complex structure that is functionally independent from the duodenal musculature. Endoscopic manometric studies have demonstrated that the human sphincter of Oddi creates a high-pressure zone between the bile duct and the duodenum. The sphincter regulates the flow of bile and pancreatic juice into the duodenum and also prevents the regurgitation of duodenal contents into the biliary tract. These functions are achieved by keeping pressure within the bile and pancreatic ducts higher than duodenal pressure. The sphincter of Oddi also has very high-pressure phasic contractions, which may play a role in preventing the regurgitation of duodenal contents into the biliary tract.

Both neural and hormonal factors influence the sphincter of Oddi. In humans, sphincter of Oddi pressure and phasic wave activity diminish in response to cholecystokinin. Thus, sphincter pressure relaxes after a meal, allowing the passive flow of bile into the duodenum. During fasting, high-pressure phasic contractions of the sphincter of Oddi persist through all phases of the MMC. However, recent animal studies suggest that sphincter of Oddi phasic waves do vary to some degree in concert with the MMC. Thus, sphincter of Oddi activity is undoubtedly coordinated with the partial gallbladder emptying and increases in bile flow that occur during phase III of the MMC. This activity may be a preventative mechanism against the accumulation of biliary crystals during fasting.⁴

Neurally mediated reflexes link the sphincter of Oddi with the gallbladder and stomach to coordinate the flow of bile and pancreatic juice into the duodenum. The cholecystosphincter of Oddi reflex allows the human sphincter to relax as the gallbladder contracts. Similarly, antral distention causes both gallbladder contraction and sphincter relaxation.

GALLSTONE PATHOGENESIS

Gallstone Types

Gallstones represent a failure to maintain certain biliary solutes, primarily cholesterol, and calcium salts in a solubilized state. Gallstones are classified by their cholesterol content as either cholesterol or pigment stones. Pigment stones are further classified as either black or brown (Fig. 60.1). Pure cholesterol gallstones are uncommon (10%), with most cholesterol stones containing calcium salts in their center, or nidus. In most American populations, 70% to 80% of gallstones are cholesterol, and black pigment stones account for most of the remaining 20% to 30%.

- 1 An important biliary precipitate in gallstone pathogenesis is biliary "sludge," which refers to a mixture of cholesterol crystals, calcium bilirubinate granules, and a mucin gel matrix. Biliary sludge has been observed clinically in prolonged fasting states or with the use of long-term total parenteral nutrition

FIGURE 60.1. A: Cholesterol gallstones. B: Black pigment gallstones. C: Brown pigment gallstones.

(TPN). Both of these conditions are also associated with gallstone formation. The finding of macromolecular complexes of mucin and bilirubin, similar to biliary sludge in the central core of most cholesterol gallstones, suggests that sludge may serve as the nidus for gallstone growth.

3 Cholesterol Gallstones. The pathogenesis of cholesterol gallstones is clearly multifactorial but essentially involves four factors: (a) cholesterol supersaturation in bile, (b) crystal nucleation, (c) gallbladder dysmotility, and (d) gallbladder absorption/secretion. For many years, gallstones were thought to result primarily from a defect in the hepatic secretion of biliary lipids. More recently, it has become increasingly clear that gallbladder mucosal and motor function also play key roles in gallstone formation.

Biliary Lipids. The key to maintaining cholesterol in solution is the formation of both micelles, a bile salt–phospholipid–cholesterol complex, and cholesterol–phospholipid vesicles (Fig. 60.2). Present theory suggests that in states of excess cholesterol production, these large vesicles may also exceed their capability to transport cholesterol, and crystal precipitation may occur. Cholesterol solubility depends on the relative concentration of cholesterol, bile salts, and phospholipid. By plotting the percentages of each component on triangular coordinates, the micellar zone in which cholesterol is completely soluble can be demonstrated (Fig. 60.3). In the area above the curve, bile is supersaturated with cholesterol, and precipitation of cholesterol crystals can occur.

Cholesterol Crystallization. Cholesterol supersaturation is present in many normal humans without gallstones. As bile is concentrated in the gallbladder, a net transfer of phospholipids

and cholesterol from vesicles to micelles occurs. The phospholipids are transferred more efficiently than cholesterol, leading to cholesterol enrichment of the remaining vesicles. These cholesterol-rich vesicles aggregate to form large multilamellar liquid vesicles that then precipitate cholesterol monohydrate crystals. Several pronucleating factors including mucin glycoproteins, immunoglobulins, and transferrin accelerate the precipitation of cholesterol in bile.

FIGURE 60.2. Phases of cholesterol in bile.

FIGURE 60.3. Equilibrium phase diagram for bile salt-lecithin-cholesterol-water at a concentration of 10% solids, 90% water. The monomeric phase is not depicted as a phase because it exists at the same concentration throughout. The one-phase zone contains only micelles. Several other zones exist, but only the two on the left above the one-phase zone apply to human gallbladder bile, and both contain cholesterol monohydrate crystals at equilibrium.

Gallbladder Motility. For gallstones to cause clinical symptoms, they must obtain a size sufficient to produce mechanical injury to the gallbladder or obstruction of the biliary tree. Growth of stones may occur in two ways: (a) progressive enlargement of individual crystals or stones by deposition of additional insoluble precipitate at the bile-stone interface, or (b) fusion of individual crystals or stones to form a larger conglomerate. In addition, defects in gallbladder motility increase the residence time of bile in the gallbladder, thereby playing a role in stone formation. Gallstone formation occurs in clinical states with gallbladder stasis, as seen with prolonged fasting, with the use of long-term parenteral nutrition, after vagotomy, in diabetic patients, and in patients with somatostatin-producing tumors or in those receiving long-term somatostatin therapy.

Gallbladder Absorption/Secretion. As noted previously, the gallbladder is a very effective absorptive organ, and a normal function of the gallbladder is to concentrate and acidify bile. For many years, three factors have been thought to be key in cholesterol gallstone pathogenesis: cholesterol supersaturation, cholesterol crystallization, and biliary motility. However, a fourth factor, gallbladder absorption/secretion, also may be key to gallstone formation. Alterations in sodium, chloride, bicarbonate, and water absorption may alter the milieu for cholesterol saturation and crystal formation as well as for calcium precipitation.²

Pigment Gallstones

Black Pigment Stones. With the recognition that calcium salts are present in most, if not all, cholesterol gallstones, renewed interest has developed in the events leading to the precipitation of calcium with the anions, bilirubin, carbonate, phosphate, or palmitate. Precipitation of these anions as insoluble calcium salts serves as a nidus for cholesterol stone formation. Furthermore, calcium bilirubinate and calcium palmitate also form major components of pigment gallstones. Pigment gallstones are classified as either black or brown pigment stones. Black pigment stones are typically tarry and frequently are associated with hemolytic conditions or cirrhosis. In hemolytic states, the bilirubin load and concentration of unconjugated bilirubin increase. These stones are usually not associated with infected bile and are located almost exclusively in the gallbladder.

Brown Pigment Stones. In contrast to black pigment stones, brown pigment stones are earthy in texture and are typically

found in the bile ducts, especially in Asian populations. Brown stones often contain more cholesterol and calcium palmitate than black stones and occur as primary common duct stones in Western patients with disorders of biliary motility and associated bacterial infection. In these settings, bacteria-producing slime and bacteria containing the enzyme glucuronidase cause enzymatic hydrolysis of soluble conjugated bilirubin glucuronide to form free bilirubin, which then precipitates with calcium.

GALLSTONE INCIDENCE AND RISK FACTORS

Incidence

Cholesterol gallstones account for 70% to 80% of all stones in Western industrialized countries. Their prevalence increases with patient age. Stones are uncommon in patients younger than age 20 years, but a sharp increase is noted, especially in women, with each decade to approximately age 70 years (Fig. 60.4). Approximately 20% of women and 10% of men have stones by age 60 years. Collectively, approximately 12% of Americans or 36 million men and women harbor gallstones. In certain populations, such as Native Americans, the incidence is extremely high, especially in women. In Chileans and Bolivians of Indian ancestry, gallstones are also very common, and they are associated with a high incidence of gallbladder cancer. In fact, gallbladder cancer is the most common gastrointestinal cancer in these countries. In the United States, the prevalence of stones is highest in Mexican American women (26%), and the prevalence in white women (17%) is higher than in black women (14%).⁵

Risk Factors

Gallstones are more common in women, especially those who have had multiple pregnancies, are taking birth control pills, are obese, are undergoing rapid weight loss, or have elevated serum triglyceride levels. Diet plays an important role in cholesterol supersaturation. Cholesterol gallstones do not form in vegetarians. Cholesterol gallstones are common in populations consuming a Western diet, which is relatively high in overall calories as well as animal fats and carbohydrates. The incidence of cholesterol gallstones rises in a population as it shifts

FIGURE 60.4. Influence of age and gender on gallstone incidence. (After the National Health and Nutrition Examination and Survey III [1988–1994]. The National Center for Health Statistics, Division of Health Examination Studies, Centers for Disease Control and Prevention, October 1996.)

TABLE 60.2**NATURAL HISTORY OF GALLSTONES**

■ DEGREE OF SYMPTOMS	■ SYMPTOMS REQUIRING CHOLECYSTECTOMY	■ COMPLICATIONS OF GALLSTONES
Asymptomatic	1%–2%/y	1%–2%/y
Mild symptoms	6%–8%/y	1%–3%/y
Symptomatic	5%–30%/y	7%/y

to a higher consumption of dietary fat. Diabetic patients also have an increased incidence of gallstones, which may be caused, in part, by alterations in gallbladder motor function and/or absorption/secretion. Gallstones also are known to occur more frequently in certain families. However, the genetic factors underlying this phenomenon have not been elucidated. Nevertheless, current data suggest that approximately 30% of the risk for gallstone formation is hereditary whereas 70% is environmental, with diet being the primary environmental factor.⁶

As mentioned previously, prolonged fasting, TPN, ileal resection, vagotomy, hemolytic states, and cirrhosis are additional risk factors, and many of these factors lead to black pigment stone formation. Finally, bile duct stasis, as occurs with biliary strictures, congenital cysts, chronic pancreatitis, sclerosing cholangitis, and perivaterian duodenal diverticula, is the primary risk factor for brown pigment stone formation.

NATURAL HISTORY OF GALLSTONES

An understanding of the natural history of gallstone disease is necessary for the appropriate management of patients with cholelithiasis. The presence or absence of symptoms remains the most important factor in the determination of the natural history of gallstones. Gallstone disease can be considered as a spectrum of clinical entities that includes asymptomatic gallstones, symptomatic gallstones, and complicated gallstone disease. The complications of gallstone disease include (a) acute cholecystitis, (b) choledocholithiasis with or without cholangitis, (c) gallstone pancreatitis, (d) gallstone ileus, and (e) gallbladder carcinoma.

Asymptomatic Gallstones

Asymptomatic gallstones are often discovered at the time of laparotomy or during abdominal imaging for nonbiliary dis-

ease. The vast majority of patients with gallstones are asymptomatic. The stones remain in the gallbladder and do not obstruct the cystic duct. As a result, the gallbladder fills and empties normally, and the gallstones remain silent. Over time, asymptomatic gallstones can progress to symptomatic disease. Symptomatic gallstones usually present with what is termed *biliary colic*, right upper quadrant or epigastric abdominal pain that typically develops postprandially and may be associated with nausea and vomiting. The pain results from the impaction of a gallstone at the neck of the gallbladder or cystic duct. Studies that have followed asymptomatic patients have shown that 20% to 30% of patients become symptomatic within 20 years.^{7,8} Approximately 1% to 2% of asymptomatic individuals with gallstones per year develop serious symptoms or complications related to their gallstones (Table 60.2). The longer stones remain silent, the less likely symptoms are to develop. In addition, almost all patients will develop symptomatic disease before developing one of the complications of gallstones. Therefore, prophylactic cholecystectomy is not generally indicated in patients with asymptomatic gallstones.

In select groups of patients, however, prophylactic cholecystectomy should be considered (Table 60.3). Children with gallstones almost always develop symptoms and should be considered for early cholecystectomy. In patients with sickle cell disease, cholecystitis can precipitate a crisis with substantial operative risks. Therefore, these patients are best treated with elective cholecystectomy. A nonfunctioning gallbladder usually indicates advanced disease with more than 25% of these patients developing symptoms that require cholecystectomy. Large gallstones (>2.5 cm) are more frequently associated with acute cholecystitis and gallbladder carcinoma, and prophylactic cholecystectomy may also be indicated in these patients. In the past, the presence of a porcelain gallbladder (calcified gallbladder wall) was thought to be associated with a 25% risk of malignant transformation, and prophylactic cholecystectomy has been recommended. More recent data suggest that the true risk may be less than 5%,^{9,10} but is still high enough to justify cholecystectomy. Patients with a long

TABLE 60.3**INDICATIONS/CONTRAINDICATIONS****INDICATIONS FOR PROPHYLACTIC CHOLECYSTECTOMY**

Pediatric gallstones
Congenital hemolytic anemia
Gallstones >2.5 cm in diameter
Calcified (porcelain) gallbladder
Bariatric surgery
Incidental gallstones found during intra-abdominal surgery
Long common channel of bile and pancreatic ducts
No access to medical care

common channel between the bile and pancreatic ducts also are at significant risk for gallbladder cancer and should undergo prophylactic cholecystectomy.

In obese patients in whom gallstones have already developed and who undergo bariatric surgery, cholecystectomy may be indicated because in a large number of these patients symptoms develop that are difficult to distinguish from symptoms caused by complications of their primary operation. Moreover, in 36% of patients who require gastric bypass operations for morbid obesity who did not have gallstones previously, gallstones developed within 6 months of their operation during the period of rapid weight loss.¹¹ Even more remarkable is that symptoms develop in 40% of these patients and 28% require cholecystectomy during the first year after operation. Prophylactic cholecystectomy adds minimal morbidity and mortality risks to most bariatric operations and is clearly indicated in patients with gallstones. Finally, acute cholecystitis is a potentially life-threatening condition in immunosuppressed patients. For this reason, prophylactic cholecystectomy has been recommended prior to major organ transplantation.

Prophylactic cholecystectomy is not indicated in patients with diabetes and asymptomatic gallstones. Although diabetic patients have an increased risk of surgery with emergent cholecystectomy, recent studies have shown that they also have an increased risk with elective cholecystectomy. This increased risk is related to comorbid conditions, not to the diabetes itself. Furthermore, no evidence suggests that asymptomatic diabetics are at increased risk to develop complications of gallstone disease.

Symptomatic Gallstones

Patients with mild symptoms (intermittent biliary colic) are at higher risk for developing gallstone-related complications or requiring cholecystectomy than asymptomatic patients who have gallstones. Approximately 1% to 3% of mildly symptomatic patients per year will develop gallstone-related complications, and at least 6% to 8% per year will require a cholecystectomy to manage their gallbladder symptoms. The diagnosis of symptomatic gallstones requires the presence of characteristic symptoms and the documentation of gallstones on diagnostic imaging.

The primary symptom associated with chronic cholecystitis or symptomatic cholelithiasis is pain. This pain is often referred to as *biliary colic*, a term that is inaccurate and suggests that the pain related to gallstones is intermittent and spasmodic like other colicky pain. In fact, obstruction of the cystic duct results in a progressive increase in tension in the gallbladder wall, leading to constant pain in the majority of patients. The pain is usually located in the right upper quadrant and/or epigastrium and frequently radiates to the back and right scapula. The intensity of the pain is often severe enough that patients often seek immediate medical attention with the first episode. Classically, the pain of biliary colic occurs following fatty meals, although this situation does not occur in most cases. An association with meals is present in only 50% of patients, and in these patients, the pain often develops more than 1 hour after eating. In the remaining patients, the pain is not temporally related to meals and often begins at nighttime, waking the patient from sleep.

The duration of pain is typically 1 to 5 hours. The attacks rarely persist for more than 24 hours and are rarely shorter than 1 hour. Pain lasting beyond 24 hours suggests that acute inflammation or cholecystitis is present. The attacks are often discrete and severe enough that the patient can accurately recall and number them. The episodes of biliary colic are usually less frequent than one episode per week. Other symptoms such as nausea and vomiting often accompany each episode (60% to 70% of cases). Bloating and belching are also present in 50% of patients. Fever and jaundice occur much less frequently with simple biliary colic.

Atypical pain is common. Sometimes the pain is continuous rather than episodic. The pain may be located predominantly in the back or the left upper or right lower quadrant. Not all attacks are necessarily severe, and some patients do not relate their pain to meals or time of day. The less typical the pain, the more carefully the clinician should search for another cause, even in the presence of stones—causes such as renal colic, peptic ulcer disease, hiatal hernia, abdominal wall hernia, liver tumors, and disease of the small and large intestine. Treatment of atypical biliary colic is appropriate when other causes of pain have been eliminated.

Complicated Gallstones

Acute cholecystitis occurs in approximately 10% to 20% of patients with symptomatic gallstones and results from occlusion of the cystic duct by one or more gallstones. Obstruction of the cystic duct incites an inflammatory response in the gallbladder and can lead to significant complications, including gangrene, empyema, emphysematous cholecystitis, perforation, or cholecystenteric fistula. Historically, choledocholithiasis (CBD stones) was present in 8% to 15% of patients with symptomatic gallstones. However, with the advent of laparoscopic cholecystectomy, the median age for cholecystectomy and the incidence of choledocholithiasis have reduced. The incidence of CBD stones varies with age and is less than 5% in younger patients and more than 20% in older patients with gallstones. CBD stones typically develop in the gallbladder and subsequently enter the CBD via the cystic duct. CBD stones may cause secondary biliary cirrhosis, cholangitis, and pancreatitis.

DIAGNOSTIC IMAGING

Abdominal Plain Films

In general, abdominal plain films have a low yield in diagnosing biliary tract problems. Plain films are most useful in diagnosing other causes of acute abdominal pain such as a perforated viscus or a bowel obstruction. Only approximately 15% of gallstones contain sufficient calcium to appear radiopaque on a plain radiography. Rarely, abdominal films may show a calcified gallbladder wall or pneumobilia that may aid in the diagnosis of biliary disease.

Ultrasound

Transabdominal ultrasound is the radiologic procedure of choice for identifying gallstones and bile duct dilation. Ultrasound is noninvasive, inexpensive, and widely available. Patients should receive nothing by mouth for several hours prior to performing an ultrasound examination so that the gallbladder is fully distended. Gallstones create echoes that are reflected back to the ultrasound probe. The ultrasound waves cannot penetrate the stones; therefore, acoustic shadowing is seen posterior to the stones (Fig. 60.5). In addition, gallstones that are free-floating in the gallbladder will move to a dependent position when the patient is repositioned during scanning. When these two features are present, the accuracy of ultrasound at diagnosing gallstones approaches 100%. Echoes without shadows may be caused by gallbladder polyps.

Several features lower the diagnostic accuracy of ultrasound in detecting gallstones. Small gallstones may not demonstrate an acoustic shadow. Furthermore, a lack of fluid (bile) around the gallstones (stone impacted in cystic duct, gallbladder filled with gallstones) also impairs their detection. In addition, an ileus with increased abdominal gas as occurs with acute cholecystitis may hamper gallbladder visualization. Overall, the false-negative rate for ultrasound in detecting

FIGURE 60.5. Abdominal ultrasound of gallbladder with multiple echogenic gallstones.

gallstones is approximately 5% but may increase to 15% with acute cholecystitis.

Ultrasound also can demonstrate dilatation of the intrahepatic or proximal extrahepatic bile ducts with at least an 80% accuracy rate.¹² The normal extrahepatic bile duct diameter is less than 10 mm, and normal intrahepatic duct diameter is less than 4 mm. Dilated ducts may signify the presence of stones in the CBD.

Cholescintigraphy

Cholescintigraphy provides a noninvasive evaluation of the liver, gallbladder, bile duct, and duodenum with both anatomic and functional information. ^{99m}Techetium-labeled iminodiacetic acid derivatives (hepatic 2,6-dimethyl-iminodiacetic acid [HIDA], diisopropyl-acetanilidoiminodiacetic acid, P-isopropylacetanilido-iminodiacetic acid) are injected intravenously, rapidly extracted from the blood, and excreted into the bile. These radionuclide scans provide functional information about the liver's ability to excrete radiolabeled substances into a nonobstructed biliary tree. Uptake by the liver, gallbladder, CBD, and duodenum should all be present after 1 hour. Slow uptake of the tracer by the liver suggests hepatic parenchymal disease. Filling of the gallbladder and CBD with delayed or absent filling of the intestine suggests an obstruction at the ampulla.

The primary use of cholescintigraphy is in the diagnosis of acute cholecystitis. Although used less frequently for this indication because of the availability and accuracy of ultrasound, cholescintigraphy demonstrates the presence of cystic duct obstruction, which is invariably present in acute cholecystitis. Nonvisualization of the gallbladder 1 hour after the injection of the radioisotope with filling of the CBD and duodenum is consistent with total or partial cystic duct obstruction and acute cholecystitis. The sensitivity and specificity of cholescintigraphy for diagnosing acute cholecystitis are each about 95%. False-positive results are increased in the setting of gallbladder stasis as in critically ill patients or in patients on parenteral nutrition.

Computed Tomography/Magnetic Resonance Imaging

Abdominal computed tomography (CT) is less sensitive in diagnosing gallstones than ultrasound. Calcified gallstones are visualized in approximately 50% of patients. The role of CT

scanning is primarily limited to the diagnosis of complications of gallstone disease such as acute cholecystitis (gallbladder wall thickening, pericholecystic fluid), choledocholithiasis (intrahepatic and extrahepatic bile duct dilation), pancreatitis (pancreatic edema and inflammation), and gallbladder cancer. Magnetic resonance imaging also has been shown to be highly sensitive in the diagnosis of both gallstones and common duct stones when T2-weighted images are obtained.

TREATMENT

Nonoperative Therapy

The nonsurgical options for the treatment of gallstone disease include oral dissolution therapy with the bile acids, such as ursodeoxycholic acid; contact dissolution therapy with organic solvents (methyl tert-butyl ether); and extracorporeal shock wave biliary lithotripsy. These treatments are rarely used today. Oral dissolution therapy is indicated in symptomatic patients with cholesterol gallstones and a functioning gallbladder. Oral bile acids are only effective in the dissolution of cholesterol gallstones and, therefore, are not indicated if stones are radiopaque or if calcifications can be detected on CT scan. In carefully selected series, complete stone dissolution can be achieved in 40% of patients; however, the recurrence rate is 50% within 5 years if therapy is stopped. Contact dissolution with organic solvents requires cannulation of the gallbladder with direct infusion of the agent into the gallbladder. Again, only cholesterol gallstones are amenable to contact dissolution, and the recurrence rate is similar to that of oral dissolution therapy. Extracorporeal shock wave lithotripsy was originally thought to be a promising nonoperative alternative for the management of symptomatic gallstones. Extracorporeal shock wave lithotripsy is a reasonable therapy for patients with single stones 0.5 to 2 cm in diameter, which have a lower recurrence rate of about 20%. Again, only a small percentage of patients with stones fit these criteria. Moreover, extracorporeal shock wave biliary lithotripsy has never been approved for gallstone dissolution by the U.S. Food and Drug Administration. Finally, the widespread application of laparoscopic cholecystectomy has greatly limited the role of all nonoperative techniques to a very select group of patients.

Operative Therapy

The operative management of gallstones has been the standard of care over the past 140 years. Cholecystectomy is the most common gastrointestinal operation performed in the United States. Since the introduction of laparoscopic cholecystectomy, the number of cholecystectomies performed in the United States has increased from approximately 500,000 per year to 750,000 per year. John Stough Bobb of Indianapolis is credited with performing the first operation on the biliary tract. In 1867, Bobb explored a 32-year-old woman with a large abdominal mass and discovered a massive gallbladder hydrops. A cholecystotomy was made, the gallstones removed, and the gallbladder sutured closed. Fifteen years later, in 1882, Carl Langenbuch of Berlin is credited with performing the first cholecystectomy in a 43-year-old man with a 16-year history of biliary colic. In the late 1980s, German and French surgeons described the first laparoscopic cholecystectomies. Currently, more than 90% of cholecystectomies in the United States are performed laparoscopically.

Laparoscopic Cholecystectomy. Symptomatic cholelithiasis is the main indication for laparoscopic cholecystectomy. As experience with advanced laparoscopy has increased, however, many surgeons will attempt a laparoscopic cholecystectomy in situations of complicated gallstone disease. Contraindications

to laparoscopic cholecystectomy include the inability of the patient to withstand a general anesthetic, severe bleeding disorders, and end-stage liver disease. In addition, patients with severe chronic obstructive pulmonary disease or congestive heart failure may not tolerate the pneumoperitoneum required for performing laparoscopic surgery. The technical difficulty of laparoscopic cholecystectomy is increased in several clinical settings. Laparoscopic cholecystectomy can be performed safely in acute cholecystitis albeit with a higher conversion rate and operative time than in the elective setting. Morbid obesity, once thought to be a relative contraindication to the laparoscopic approach, is not associated with a higher conversion rate. Longer trocars and instruments and an increase in intra-abdominal pressure may be helpful in these patients. Prior upper abdominal surgery may increase the difficulty of or preclude laparoscopic cholecystectomy. Elective laparoscopic cholecystectomy also has been completed safely in patients with well-compensated cirrhosis (Child's class A and B), although difficulty retracting the firm liver and increased bleeding from collaterals have been noted.

Patients undergoing laparoscopic cholecystectomy are prepared and draped in a similar fashion to open cholecystectomy. Conversion to an open operation is necessary in up to 3% of patients undergoing elective cholecystectomy and up to 25% of patients undergoing laparoscopic cholecystectomy for acute cholecystitis. A Foley catheter and orogastric tube are inserted to avoid inadvertent injury and improve exposure. Either an open or closed technique can be used to establish a pneumoperitoneum. With the open technique, a small incision is made at the umbilicus, and a blunt cannula (Hasson cannula) is inserted into the peritoneal cavity and anchored to the fascia. In the closed technique a Veress needle is inserted into the peritoneal cavity through a supraumbilical incision and used for insufflation. An 11-mm trocar is inserted through the supraumbilical incision once a pneumoperitoneum is established. A 30-degree laparoscope is then inserted through the umbilical port, and an examination of the peritoneal cavity is performed. An 11-mm operating port is placed subxiphoid, and two additional 5-mm trocars are positioned subcostally in the right upper quadrant in the midclavicular and anterior axillary lines. Single port cholecystectomy is currently under development and may become the procedure of choice in the future.

The two 5-mm ports are used for grasping the gallbladder and exposing the gallbladder and cystic duct (Fig. 60.6). The

FIGURE 60.6. Trocar placement for laparoscopic cholecystectomy. The laparoscope is placed through a 10-mm port just above the umbilicus. Additional ports are placed in the epigastrium, subcostally in the midclavicular, and near the anterior axillary lines.

FIGURE 60.7. Incorrect (A) and correct (B) methods of retracting the gallbladder. Incorrect retraction brings the cystic and common ducts into alignment and makes them appear as one.

medial 5-mm cannula is used to grasp the gallbladder infundibulum and retract it laterally to further expose the triangle of Calot. Traction on the fundus should be upward toward the patient's head, and traction on the Hartmann pouch laterally to the right. This combination "disaligns" the common duct and cystic duct so that they appear as distinct structures. Incorrect traction aligns the ducts so that they appear as a continuous structure and as a consequence the chance of biliary injury is increased (Fig. 60.7). The junction of the gallbladder and cystic duct is identified by stripping the peritoneum off the gallbladder neck and removing any tissue surrounding the gallbladder neck and proximal cystic duct. This dissection is continued until the triangle of Calot is cleared of all fatty and lymphatic tissue and the gallbladder infundibulum is elevated off of the liver bed (Fig. 60.8). Visualization of this "critical view" is important in preventing injury to the bile ducts. At this point two structures (cystic artery and cystic duct) should be seen entering the gallbladder. Performance of a cholangiogram may be a factor in avoiding

FIGURE 60.8. The "critical view" of safety. The triangle of Calot is dissected free of all tissue except for the cystic duct and artery, and the base of the liver bed is exposed. When this view is achieved, the two structures entering the gallbladder can only be the cystic duct and artery. Visualization of the common bile duct is not necessary. (After Strasberg SM, Hertl M, Soper NJ. An analysis of the problem of biliary injury during laparoscopic cholecystectomy. *J Am Coll Surg* 1995;180:101.)

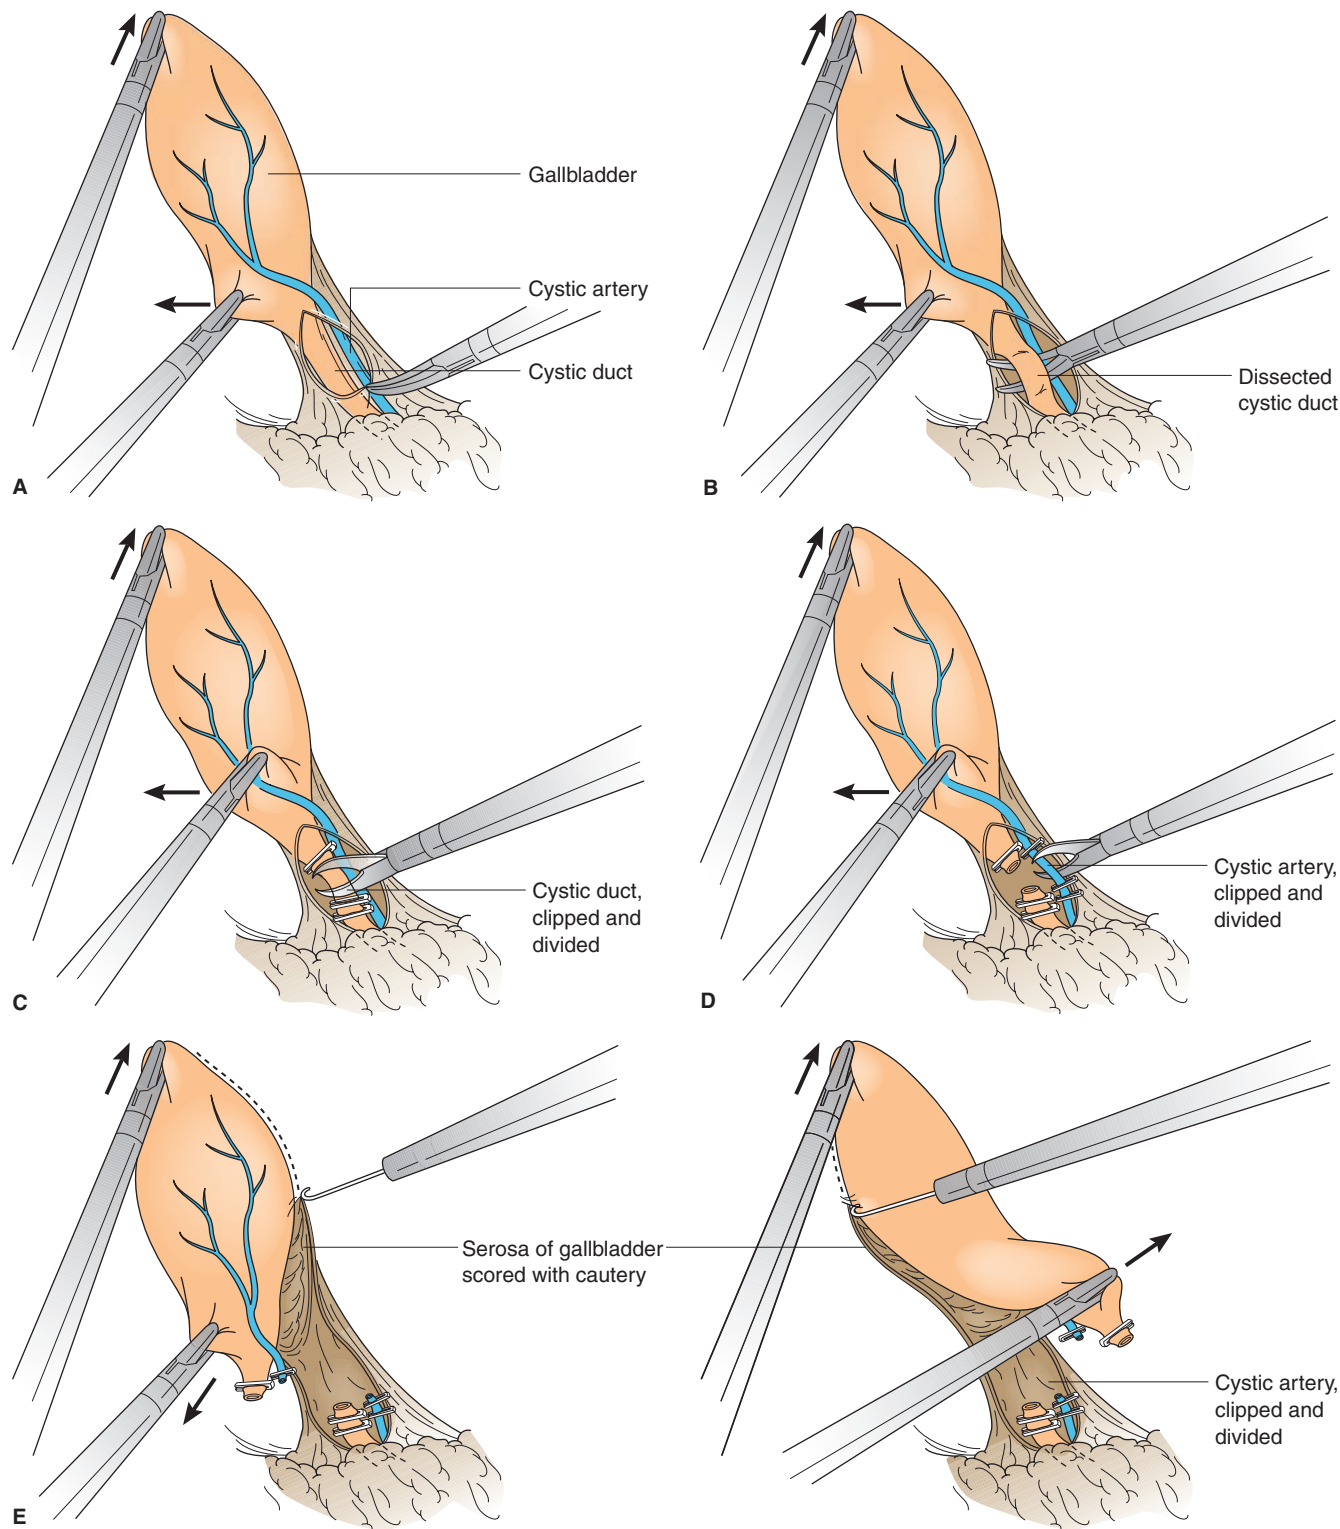

FIGURE 60.9. A: The peritoneum overlying the cystic duct–gallbladder junction is opened with blunt dissection. B: The cystic duct is isolated. C: The cystic duct is clipped proximal and distal and divided with the hook scissors. D: The cystic artery is dissected, clipped, and divided. E: The gallbladder is dissected from the liver by scoring the serosa with electrocautery.

biliary injury.¹³ Once the cystic duct is identified, an intraoperative cholangiogram may be performed by placing a ligating clip proximally on the cystic duct, incising the anterior surface of the duct, and passing a cholangiogram catheter into the cystic duct. Once the cholangiogram is completed, two clips are placed distally on the cystic duct, which is then divided (Fig. 60.9). Alternatively, the CBD may be evaluated for stones

using laparoscopic ultrasound. The sensitivity of laparoscopic ultrasound for detecting CBD stones is comparable to intraoperative cholangiography (80% to 96% vs. 75% to 99%).

The next step is the division of the cystic artery. The artery is usually encountered running parallel to and behind the cystic duct. Once identified and isolated, clips are placed proximally and distally, and the artery is divided. The peritoneum

overlying the gallbladder is placed on tension using the two grasping forceps, the peritoneum and adventitia between the gallbladder and liver are divided with the cautery, and the gallbladder is dissected out of the gallbladder fossa (Fig. 60.9). Prior to removing the gallbladder from the liver, the operative field is carefully searched for hemostasis and adequate placement of the cystic duct and artery clips is confirmed. The gallbladder is then dissected off the liver and is usually removed through the umbilical port. The fascial defect and skin incision may need to be enlarged to remove the gallbladder and contained gallstones. If the gallbladder has been entered during the dissection or if it is acutely inflamed or gangrenous, the gallbladder should be placed in a plastic specimen retrieval bag prior to removing it from the peritoneal cavity.^{14,15}

Elective laparoscopic cholecystectomy can be safely performed as an outpatient procedure.¹⁶ Among patients selected for outpatient management, 77% to 97% of patients can be successfully discharged the same day. Factors contributing to overnight admission include uncontrolled pain, nausea and vomiting, operative duration greater than 60 minutes, and cases completed late in the day.

Routine operative cholangiography has been advocated to avoid ductal injury. However, opinion on the subject is sharply divided. Biliary injuries occur less frequently in the hands of surgeons who perform operative cholangiography routinely. However, in about 50% of ductal injuries, a cholangiogram fails to prevent the injury although abnormal anatomy is present (i.e., cholangiograms are often incorrectly interpreted). The indications for intraoperative cholangiography, when it is performed selectively, are known choledocholithiasis, a history of jaundice, a history of pancreatitis, a large cystic duct and small gallstones, any abnormality in preoperative liver function tests, and dilated biliary ducts on preoperative sonography. Provided these indications are carefully followed, selective cholangiography may be as effective in detecting clinically relevant stones as routine cholangiography.

Serious complications of laparoscopic cholecystectomy are rare, the mortality rate being less than 0.3%. As cholecystectomy rates have risen, however, the total number of deaths has not decreased.¹⁷ The single greatest problem in laparoscopic cholecystectomy is biliary injury. The incidence of major bile duct injury following laparoscopic cholecystectomy is between 0.3% and 0.6%; but if all bile leaks are considered, the injury rate in these reports ranges from 0.6% to 1.5%, which is three to four times the injury rate at open surgery.¹⁸ Major vascular injuries to the hepatic arteries, especially the right hepatic artery, may occur in association with biliary injuries and sometimes lead to intraoperative blood loss. Isolated vascular injuries to hepatic vessels are rare. Although the increase in cholecystectomy rates means that the total number of deaths from cholecystectomy has not decreased, an individual patient's risk for death is smaller.

Spillage of stones into the peritoneal cavity during laparoscopic cholecystectomy occurs in 10% or more of cases. Leaving stones in the peritoneal cavity may not be innocuous.¹⁹ Intra-abdominal abscess, subcutaneous abscess, and later discharge of stones through the abdominal wall or through the lung and trachea have all been described. Every attempt should be made to remove spilled stones by picking and irrigating them out. Clearance is usually quite successful with the use of retractors to lift the liver and the 30-degree laparoscope, which allows the depths of the recess between liver and kidney to be visualized. Laparoscopic ultrasonography may be useful to detect stones. Large stones or massive spills should be cleaned up by laparotomy if necessary. If concern exists that stones have been left behind, the patient should be informed.

As in open cholecystectomy, a gallbladder containing an unsuspected cancer is excised 1 to 3 times per 1,000 laparoscopic cholecystectomies. Therefore, a good practice is to open the gallbladder and inspect it and obtain frozen sections if a suspect lesion is observed. If cancer is suspected, the gallblad-

der should be extracted in an impermeable bag. If a cancer is discovered, further surgery may be indicated.

Open Cholecystectomy. Open cholecystectomy can be performed through either an upper midline or right subcostal (Kocher) incision. Identification and division of the cystic duct and artery initially limit bleeding from the gallbladder for the remainder of the dissection. With lateral traction on the gallbladder neck, the peritoneum overlying the triangle of Calot is incised, and the cystic duct is identified and ligated distally. A cholangiogram is performed at this time if indicated. The cystic duct is then ligated proximally and divided. Similarly, the cystic artery is ligated and divided after carefully tracing it onto the gallbladder. If the anatomy cannot be clearly identified, the gallbladder should be dissected from the fundus downward toward the gallbladder neck, making the ductal and vascular anatomy easier to identify. The gallbladder is dissected out of the gallbladder bed by incising the overlying peritoneum with cautery.

CLINICAL MANIFESTATIONS

Chronic Calculous Cholecystitis

Pathogenesis. The term *chronic cholecystitis* implies an ongoing or recurrent inflammatory process involving the gallbladder. In most patients (more than 90%), gallstones are the causative factor and lead to recurrent episodes of cystic duct obstruction manifest as biliary pain or colic. Over time, these recurrent attacks can lead to scarring and a nonfunctioning gallbladder. Histopathologically, chronic cholecystitis is characterized by an increase in subepithelial and subserosal fibrosis and a mononuclear cell infiltrate.

Clinical Presentation. The primary symptom associated with chronic cholecystitis or symptomatic cholelithiasis is pain, often labeled *biliary colic*. The pain is usually located in the right upper quadrant and/or epigastrium and frequently radiates to the right upper back, to the right scapula, or between the scapulae (as noted in the previous discussion of symptomatic gallstones). Other symptoms such as nausea and vomiting often accompany each episode (60% to 70% of cases). The physical examination is usually completely normal in patients with chronic cholecystitis, particularly if they are pain-free. During an episode of biliary colic, mild right upper quadrant tenderness may be present. Laboratory values such as serum bilirubin, transaminases, and alkaline phosphatase usually are normal in patients with uncomplicated gallstones.

Diagnosis. The diagnosis of chronic calculous cholecystitis requires two findings: abdominal pain consistent with biliary colic and the presence of gallstones. The presence of symptoms (usually pain) attributable to the gallbladder is necessary to consider any treatment for gallstones. Patients without symptoms (approximately two thirds of patients with gallstones) develop symptoms at a low rate and complications of gallstones at an even lower rate (as noted in the previous discussion of natural history). In most cases treatment is not necessary in these asymptomatic patients. Ultrasound is sensitive (95% to 98%) for documenting the presence of gallstones and also provides additional anatomic information, including the presence of polyps, the diameter of the CBD, and any hepatic parenchymal abnormalities. Gallstones are occasionally identified on abdominal radiographs (15%) or CT scans (50%) because gallstones contain enough calcium to be visualized.

5 Management. The treatment of choice for patients with symptomatic gallstones is elective laparoscopic cholecystectomy. The mortality of laparoscopic cholecystectomy is less than 0.3%, with cardiovascular complications being the most

frequent cause of death. The most significant complication following laparoscopic cholecystectomy is injury to the biliary tract. Overall, complications occur in fewer than 10% of patients. Conversion to an open cholecystectomy is necessary in less than 3% of patients undergoing laparoscopic cholecystectomy for chronic cholecystitis. Conversion rates are increased in elderly, obese, and male patients.

The long-term results of laparoscopic cholecystectomy in appropriately selected patients with chronic cholecystitis are excellent. More than 90% of patients with typical biliary pain and gallstones are symptom-free following cholecystectomy. For patients with atypical symptoms or painless dyspepsia (fatty food intolerance, flatulence, belching, or bloating), the percentage of patients experiencing relief of symptoms decreases.

Acute Calculous Cholecystitis

Pathophysiology. Acute cholecystitis is the most common complication of gallstones, occurring in 15% to 20% of patients with symptomatic disease. As in biliary colic, acute cholecystitis results from a stone impaction at the gallbladder–cystic duct junction (Fig. 60.10). The extent of inflammation and the progression of acute cholecystitis are related to the duration and degree of obstruction. In the most severe cases (5% to 18%), this process can lead to ischemia and necrosis of the gallbladder wall. More frequently, the gallstone is dislodged, and the inflammation gradually resolves. Acute cholecystitis is primarily an inflammation and not an infectious process, with bacterial infection appearing as a secondary event. Approximately 50% of patients with acute cholecystitis will have positive bile cultures, with *Escherichia coli* being the most common organism.

Clinical Presentation. Patients with acute cholecystitis typically present with right upper quadrant pain that is similar to that of biliary colic. In acute cholecystitis, however, the pain is usually unremitting, may last several days, and is often associated with nausea, emesis, anorexia, and fever. On physical examination, patients with acute cholecystitis usually have a low-grade fever and exhibit localized right upper quadrant tenderness and guarding, which distinguish the episode from simple biliary colic. The presence of Murphy's sign, an inspiratory arrest during deep palpation of the right upper quadrant, is the classic physical finding of acute cholecystitis. A palpable right upper quadrant mass is appreciated in one third of

patients and usually represents omentum that has migrated to the area around the gallbladder in response to the inflammation. Severe jaundice is rare, but mild jaundice may be present—up to 6 mg/dL. Severe jaundice suggests the presence of CBD stones, cholangitis, or obstruction of the common hepatic duct by severe pericholecystic inflammation resulting from impaction of a large stone in the Hartmann pouch, which mechanically obstructs the bile duct (Mirizzi syndrome). Acute cholecystitis may coexist with choledocholithiasis or its complications (acute cholangitis and gallstone pancreatitis). The coexistence of two of these conditions often explains an unusual or atypical clinical presentation.

Laboratory evaluation can show a mild leukocytosis (white blood cell count [WBC] 12,000 to 15,000 cells/mm³). However, many patients have a normal WBC count. A white cell count greater than 20,000 should suggest further complications of cholecystitis, such as gangrene, perforation, or cholangitis. Mild elevations in serum bilirubin (<4 mg/dL), alkaline phosphatase, the transaminases, and amylase may also be seen with acute cholecystitis.

Diagnosis. Ultrasound is the most useful radiologic examination in the patient with suspected cholecystitis. First, in the patient without known gallstones, ultrasound is a sensitive test for establishing the presence or absence of gallstones. Additional findings suggestive of acute cholecystitis include thickening of the gallbladder wall (>4 mm) and pericholecystic fluid. Focal tenderness directly over the gallbladder (sonographic Murphy's sign) also is suggestive of acute cholecystitis. Ultrasound has a sensitivity and specificity of 85% and 95%, respectively, for diagnosing acute cholecystitis.

Radionuclide scanning is used less frequently for the diagnosis of acute cholecystitis but may provide additional information in the atypical case. Nonfilling of the gallbladder with the radiotracer ⁹⁹Tc-HIDA indicates an obstructed cystic duct, and in the right clinical setting is highly sensitive (95%) and specific (95%) for acute cholecystitis. Computed tomography (Fig. 60.11) occasionally is performed in evaluating the patient with abdominal pain and acute illness. CT may demonstrate evidence of acute cholecystitis, including gallbladder wall thickening, pericholecystic fluid and edema, gallstones, and air in the gallbladder or gallbladder wall (emphysematous cholecystitis), although it is less sensitive for these conditions than ultrasonography.

Management. Once the diagnosis of acute cholecystitis is made, the patient should be given nothing by mouth, and

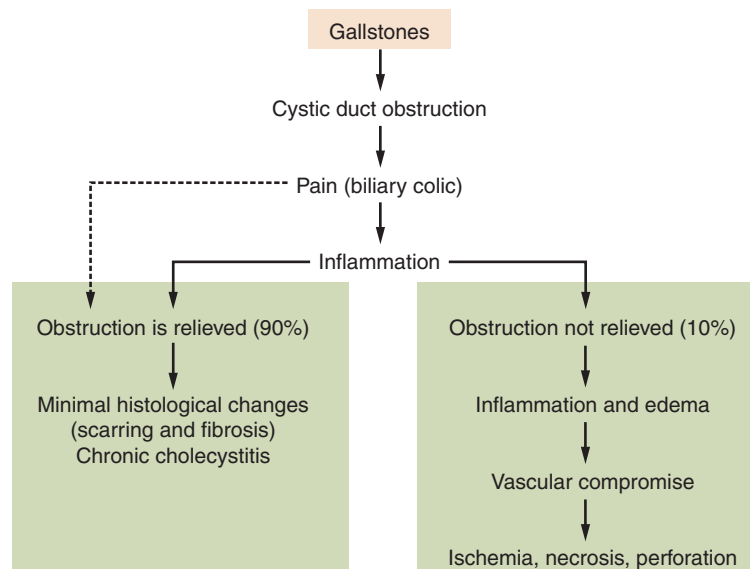

FIGURE 60.10. Pathophysiology of acute cholecystitis.

FIGURE 60.11. Computed tomography of a patient with acute cholecystitis showing gallbladder wall thickening and pericholecystic fluid.

intravenous hydration should begin. A nasogastric tube is placed if persistent nausea and vomiting or abdominal distention are present. In almost all cases, broad-spectrum antibiotics, such as a broad-spectrum penicillin, should be started and maintained into the immediate postoperative period. Parenteral analgesia also should be administered. Unfortunately, narcotics increase biliary pressure, whereas nonsteroidal analgesics, which inhibit prostaglandin synthesis, reduce gallbladder mucin production and, therefore, reduce pressure and pain.

The treatment of choice for acute cholecystitis is cholecystectomy. Open cholecystectomy had been the standard treatment for acute cholecystitis for many years. Initially, acute cholecystitis was felt to be a contraindication to laparoscopic cholecystectomy. As experience has increased, however, laparoscopic cholecystectomy clearly can be performed safely in the setting of acute cholecystitis. In prospective randomized trials, the morbidity rate, length of hospital stay, and time to return to work all have been lower in patients undergoing laparoscopic cholecystectomy than open cholecystectomy.²⁰ However, the conversion rate in the setting of acute cholecystitis (10% to 25%) is higher than with chronic cholecystitis.

The timing of cholecystectomy for acute cholecystitis has been studied for several decades. In the distant past, delayed

FIGURE 60.12. Schematic demonstration of the technique of percutaneous placement of a pigtail catheter into the gallbladder.

cholecystectomy was preferred in the setting of acute cholecystitis. Patients were initially managed nonoperatively and discharged home after their symptoms resolved. Elective cholecystectomy was then performed 6 weeks later after the acute inflammation had resolved. Several prospective randomized trials have shown that early laparoscopic cholecystectomy (within 3 days of symptom onset) can be accomplished with a similar morbidity and mortality rate as delayed cholecystectomy. Representative results are documented in Table 60.4.^{21,22} No significant differences were observed in the conversion rate to open cholecystectomy among patients undergoing early cholecystectomy versus those managed with delayed surgery. Hospital stay, and therefore cost, however, were significantly reduced in the trials in the early laparoscopic cholecystectomy group. In addition, approximately 20% of patients in the delayed surgery arms failed initial medical therapy and required operation during the initial admission or before the end of the planned cooling-off period.

Laparoscopic cholecystectomy should be performed within 24 to 72 hours of diagnosis. Early conversion to an open procedure should be considered if dissection is difficult or clear progress cannot be made by the laparoscopic technique. In certain high-risk patients whose medical conditions preclude cholecystectomy, a cholecystostomy can be performed for acute cholecystitis. Although previously performed operatively and under local anesthesia, percutaneous drainage techniques can usually be accomplished (Fig. 60.12). In most cases,

prompt improvement is seen after gallbladder drainage and appropriate antibiotics. These patients must be observed closely, however, and if improvement does not occur within 24 hours, laparotomy is indicated. Failure to improve after percutaneous cholecystostomy is usually caused by gangrene of the gallbladder or perforation. After the acute episode resolves, the patient can undergo either cholecystectomy or percutaneous stone extraction and removal of the cholecystostomy tube. The latter is an option in elderly or debilitated patients for whom a general anesthetic is contraindicated.²³

Complications of Acute Cholecystitis. Several complications of acute cholecystitis are recognized in clinical practice. These complications include empyema of the gallbladder, emphysematous cholecystitis, perforation, and cholecystenteric fistula. All of these complications can be associated with significant morbidity and mortality and, therefore, require prompt surgical intervention.

Empyema. Gallbladder empyema represents an advanced stage of cholecystitis with bacterial invasion of the gallbladder and actual pus in the lumen. Patients present with severe right upper quadrant pain, high-grade fever, rigors, and significant leukocytosis. Sepsis including cardiovascular collapse may be seen. Treatment consists of broad-spectrum antibiotics, including anaerobic coverage, and emergent cholecystectomy or cholecystostomy; however, cholecystostomy may not be adequate to relieve sepsis in patients with empyema of the gallbladder.

Emphysematous Cholecystitis. Emphysematous cholecystitis develops more commonly in males and patients with diabetes mellitus. Severe right upper quadrant pain and generalized sepsis are frequently present. Abdominal films or CT scans may demonstrate air within the gallbladder wall or lumen. Prompt antibiotic therapy to cover the common biliary pathogens including *E. coli*, *Enterococcus*, *Klebsiella*, and *Clostridia* species and emergency cholecystectomy are appropriate treatments.

Gangrene/Perforation. Gangrene of the gallbladder occurs when the wall becomes ischemic and leads to perforation. Gallbladder perforation can be categorized as being either

localized or free. The incidence of perforation in acute cholecystitis is approximately 10%. Localized perforation generally results in the formation of a pericholecystic abscess as the omentum walls off the perforation and limits it to the right upper quadrant. Free perforation is less frequent (1% of cases) and occurs if the omentum is unable to wall off the inflammatory process. Free perforation results in the spilling of bile into the peritoneal cavity and a generalized peritonitis. Perforation should be suspected if the patient's clinical course deteriorates. Evidence for perforation includes an increase in pain and tenderness, fever and chills, elevation in white blood cell count, and hypotension. These patients require aggressive fluid resuscitation, antibiotics, and emergent operative exploration. Cholecystostomy usually will not be adequate therapy for patients with gangrene or perforation of the gallbladder.

Cholecystenteric Fistula. In 1% to 2% of patients with acute cholecystitis, the gallbladder will perforate into an adjacent hollow viscus. The duodenum (79%) and the hepatic flexure of the colon (17%) are the most common sites. Generally, after the fistula forms, the episode of acute cholecystitis resolves as the gallbladder spontaneously decompresses. If a large gallstone passes from the gallbladder into the small intestine, a mechanical bowel obstruction may result, which is termed *gallstone ileus*. Gallstone ileus occurs in 10% to 15% of patients with a cholecystenteric fistula. Patients with gallstone ileus present with signs and symptoms of intestinal obstruction—nausea, vomiting, and abdominal pain. The pain may be episodic and recurrent as the impacted stone temporarily impacts in the gut lumen and then dislodges and moves distally (tumbling obstruction). A history of gallstone-related symptoms (right upper quadrant pain) may only be present in 50% of these patients. Abdominal films will demonstrate small-bowel distention and air-fluid levels and may give additional clues to the source of the obstruction (pneumobilia or a calcified gallstone distant from the gallbladder). The site of obstruction is most frequently in the narrowest part of the small intestine (ileum) or large intestine (sigmoid colon).

The initial management of gallstone ileus includes relieving the obstruction. Most frequently, this goal can be achieved by removing the gallstone through an enterotomy (Fig. 60.13). Additional gallstones should be sought as recurrent obstruction

FIGURE 60.13. A: Abdominal plain film demonstrating small-bowel obstruction secondary to gallstone ileus. Arrows show a gallstone in the right lower quadrant and air in the biliary tree. B: Operative photograph demonstrating removal of a large gallstone from the ileum.

has been reported in up to 10% of patients with gallstone ileus. Takedown of the biliary-enteric fistula and cholecystectomy may be warranted as recurrent cholecystitis and cholangitis are common in patients with a biliary-enteric fistula, and gallbladder cancer has been reported in 15% of these patients. However, in patients with a significant inflammatory process in the right upper quadrant or who are too unstable to withstand a prolonged operative procedure, the fistula can be addressed at a second laparotomy.

Acute Acalculous Cholecystitis

Acute acalculous cholecystitis accounts for 5% to 10% of all patients with acute cholecystitis. The disease often has a more fulminant course than acute calculous cholecystitis and frequently progresses to gangrene, empyema, or perforation. Acute acalculous cholecystitis usually occurs in the critically ill patient following trauma, burns, long-term parenteral nutrition, and major nonbiliary operations such as abdominal aneurysm repair and cardiopulmonary bypass. The etiology of acute acalculous cholecystitis remains unclear, although gallbladder stasis and ischemia have been most often implicated as causative factors. Stasis is common in critically ill patients not being fed enterally and may lead to colonization of the gallbladder with bacteria. Visceral ischemia also is a common denominator in patients with acute acalculous cholecystitis and may explain the high incidence of gallbladder gangrene. Decreased arteriolar and capillary filling is present in acute acalculous cholecystitis in contrast to the dilation of these vessels observed in acute calculous cholecystitis.

The symptoms and signs of acute acalculous cholecystitis are similar to acute calculous cholecystitis with right upper quadrant pain and tenderness, fever, and leukocytosis most frequently present. CT scan and ultrasound findings are similar to calculous cholecystitis and include gallbladder wall thickening and pericholecystic fluid in the absence of gallstones. Cholescintigraphy demonstrates absent gallbladder filling in acute acalculous cholecystitis; however, the false-positive rate (absent gallbladder filling without acute acalculous cholecystitis) may be as high as 40%.

Emergency cholecystectomy is the appropriate treatment once the diagnosis is established or the suspicion is high. The incidence of gangrene, perforation, and empyema exceeds 50%; therefore, cholecystectomy rather than cholecystostomy is usually required in this setting. The mortality rate for acute acalculous cholecystitis remains high (40%) in large part because of the concomitant illnesses in patients who develop this disease.

Chronic Acalculous Cholecystitis

- 7 A subgroup of patients presenting with typical symptoms of biliary colic (postprandial right upper quadrant pain, fatty food intolerance, and nausea) do not have any evidence of gallstones on ultrasound examination. Further investigations have usually been performed in these patients to exclude any other pathology. This workup often includes an abdominal CT scan, esophagogastroduodenoscopy, or even an endoscopic retrograde cholangiogram. In these patients, the diagnosis of biliary dyskinesia or chronic acalculous cholecystitis should be considered. The cholecystokinin-Tc-HIDA scan has been useful in identifying patients with this disorder. Cholecystokinin (CCK) is infused intravenously after the gallbladder has filled with the ^{99}Tc -labeled radionuclide. Twenty minutes after the administration of CCK, a gallbladder ejection fraction is calculated. An ejection fraction less than 35% at 20 minutes is considered abnormal.

Patients with symptoms of biliary colic and an abnormal gallbladder ejection fraction should be managed with a laparo-

scopic cholecystectomy. Between 85% and 94% of patients with a low gallbladder ejection fraction and symptoms of biliary colic will be asymptomatic or improved by cholecystectomy. Most of these patients have histopathologic evidence of chronic cholecystitis. Over the past 15 years, the percentage of patients undergoing cholecystectomy for acalculous cholecystitis in the United States has increased from less than 5% to more than 20% of patients having their gallbladder removed. This change parallels the obesity epidemic and may be due to abnormal gallbladder emptying as well as absorption/secretion due to fat within the gallbladder wall (cholecystosteatosis).²⁴

Sphincter of Oddi Dysfunction

Sphincter of Oddi dysfunction may be caused by either a structural or functional abnormality involving the sphincter. Fibrosis of the sphincter from gallstone migration, operative or endoscopic trauma, pancreatitis, or other nonspecific inflammatory processes can lead to elevated sphincter pressures. Elevated sphincter pressures also may present in the absence of a structural abnormality, and these cases of sphincter of Oddi dyskinesia or spasm are often associated with more diffuse abnormalities of gastrointestinal motility.²⁵

Sphincter of Oddi dysfunction should be suspected in patients with typical episodic biliary-type pain without an obvious organic cause. Approximately 1% of patients undergoing cholecystectomy are estimated to have sphincter of Oddi dysfunction. Numerous diagnostic tests have been used to diagnose sphincter of Oddi dysfunction, but none are sensitive or specific. Elevated serum amylase or transaminases may be present in patients with sphincter of Oddi dysfunction. Ultrasound evidence of sphincter of Oddi dysfunction includes a dilated (>12 mm) CBD, an increase in CBD diameter in response to cholecystokinin, or an increase in pancreatic duct diameter in response to secretin. Delayed emptying of contrast from the CBD after endoscopic retrograde cholangiopancreatography (ERCP) also is indicative of abnormal sphincter function. Endoscopic manometry also has been used to evaluate the sphincter of Oddi, and an elevated basal sphincter pressure (>40 mm Hg) has been correlated with successful response to sphincter ablation.

Both endoscopic sphincterotomy and transduodenal sphincteroplasty with transampullary septotomy have been used to manage patients with sphincter of Oddi dysfunction. Results of both treatments are similar and are more dependent on the presence of objective signs of sphincter dysfunction than on the procedure performed. The endoscopic approach avoids a laparotomy and can be performed safely in expert hands if a temporary pancreatic stent is employed to reduce the risk of pancreatitis when a pancreatic duct sphincterotomy is performed. The surgical approach (transduodenal sphincteroplasty with transampullary septotomy) has the potential advantage that mucosa-to-mucosa apposition can be achieved, minimizing the risk of scarring and restenosis. When objective evidence of sphincter dysfunction is present (elevated transaminases, delayed biliary emptying, dilated CBD, elevated basal sphincter pressure), 60% to 80% of patients will be pain-free or improved following sphincterotomy or sphincteroplasty.²⁵

Acute Cholangitis

Acute cholangitis is a bacterial infection of the biliary ductal system, which varies in severity from mild and self-limited to severe and life threatening. The clinical triad of fever, jaundice, and pain associated with cholangitis was first described in 1877 by Charcot. He postulated that stagnant bile associated with obstructive biliary pathology was a significant factor in the pathogenesis of this disease.

FIGURE 60.14. Cholangitis is caused by the combination of biliary obstruction and bactibilia. Bacteria then reflux into the hepatic veins and perihepatic lymphatics, resulting in systemic bacteremia.

8 Pathophysiology. Clinical cholangitis results from a combination of two factors: significant bacterial concentrations in the bile and biliary obstruction. Although cultures of the gallbladder and bile ducts are usually sterile, in the presence of CBD stones or other obstructing pathology the incidence of positive bile duct cultures increases. The most common organisms recovered from the bile in patients with cholangitis include *E. coli*, *Klebsiella pneumoniae*, the enterococci, and *Bacteroides fragilis*.²⁶ Nevertheless, even in the presence of high biliary bacterial concentrations, clinical cholangitis and bacteremia do not develop unless obstruction causes elevated intraductal pressures.

Normal biliary pressures range from 7 to 14 cm H₂O. In the presence of bactibilia and normal biliary pressures, hepatic vein blood and perihepatic lymph are sterile. In cases of partial or complete biliary obstruction, however, intrabiliary pressures rise to 18 to 29 cm H₂O, and organisms rapidly appear in both the blood and lymph. The fever and chills associated with cholangitis are the result of systemic bacteremia caused by cholangiovenous and cholangiolymphatic reflux (Fig. 60.14).

Etiology. The most common causes of biliary obstruction are choledocholithiasis, benign strictures, biliary enteric anastomotic strictures, and cholangiocarcinoma or perihilar malignancy. Prior to 1980, choledocholithiasis was the cause of approximately 80% of the reported cases of cholangitis. In recent years, malignant strictures have become a frequent cause of cholangitis, particularly at tertiary referral centers. Endoscopic cholangiography, percutaneous transhepatic cholangiography, and stent placement via either the endoscopic or percutaneous route are all known to cause bacteremia. These procedures are frequently performed in patients with unresectable malignant obstruction.

Clinical Presentation. Cholangitis may present with a wide spectrum of disease. Patients may have a self-limited illness and never seek attention. At the other end of the spectrum, patients with toxic cholangitis present with a severe illness, including jaundice, fever, abdominal pain, mental obtundation, and hypotension (Reynolds' pentad). Fever is the most common presenting symptom and is often accompanied by chills. Jaundice is a frequent physical finding but may be absent, especially in patients with an indwelling endopro-

thesis or biliary stent. Pain is also commonly present but is often mild. Severe pain or marked tenderness should prompt consideration of an alternate diagnosis such as acute cholecystitis. Up to 33% of East Asian patients with choledocholithiasis present with toxic cholangitis characterized by septic shock.²⁷

Diagnosis. Although cholangitis is a clinical diagnosis, laboratory tests can support evidence of biliary obstruction. Leukocytosis, hyperbilirubinemia, and elevations of alkaline phosphatase and transaminases all are common in patients with cholangitis. Radiologic studies also are helpful in confirming the diagnosis. CT, ultrasound, and magnetic resonance image scanning can provide noninvasive evidence of biliary ductal dilation, pancreatic masses, and occasionally CBD stones. Cholangiography usually is required prior to or as part of therapy. Both endoscopic and percutaneous transhepatic cholangiography are associated with a 4% to 7% incidence of cholangitis, and systemic antibiotics should be administered prior to these procedures.

Management. The initial treatment of the patient with cholangitis includes antibiotics. Some patients are only mildly ill and can be managed as outpatients with oral antibiotics. Patients with toxic cholangitis may require intensive care unit monitoring and vasopressors to support blood pressure. Most patients will require intravenous fluids and antibiotics. The antibacterial regimen should cover the common pathogens isolated from the biliary tract or be based on current or prior bile cultures.²⁸

Most patients with cholangitis respond to antibiotic therapy alone with clinical improvement; however, emergency biliary decompression may be necessary in the 15% of patients who do not respond to antibiotics within 12 to 24 hours or in patients with toxic cholangitis. Biliary decompression may be performed endoscopically or via the percutaneous transhepatic route. The selection of which procedure to perform should be based on the level and nature of the biliary obstruction. In patients with a proximal perihilar obstruction or a biliary-enteric anastomotic stricture, percutaneous drainage may be the preferred route of decompression. Choledocholithiasis and cholangitis associated with perihilar malignancies are best approached endoscopically. Endoscopic biliary drainage may include endoscopic sphincterotomy and stone extraction or simply placement of an endoscopic biliary stent in the hemodynamically unstable patient. In experienced hands, successful endoscopic CBD stone clearance can be achieved in more than 90% of patients.²⁷ In settings in which either endoscopic or percutaneous biliary drainage is not possible, CBD exploration and placement of a T-tube remains a lifesaving procedure for seriously ill patients with toxic cholangitis. However, the mortality for patients treated surgically is considerably higher than for patients successfully managed endoscopically.

Overall, the mortality rate associated with an episode of cholangitis due to CBD stones is approximately 2% but is higher in patients with toxic cholangitis (5%). Renal failure, hepatic abscess, and malignancy are all associated with higher morbidity and mortality. The success of the initial antibiotic therapy and biliary drainage is significantly lower in patients with malignant biliary obstruction, and these patients frequently require changes in antibiotic therapy and repeat biliary manipulations to adequately decompress the biliary tract.²⁸ Hepatic abscesses are frequently observed in patients with biliary pathology and should be considered in patients who do not respond to therapy. Patients with cholangitis due to CBD stones should undergo interval laparoscopic cholecystectomy within 6 to 12 weeks because the incidence of recurrent biliary symptoms is significantly higher if the gallbladder is left in situ (6% vs. 25%).²⁷

CHOLEDOCHOLITHIASIS

Classification and Etiology

CBD stones can be classified as either primary or secondary. Primary duct stones develop de novo within the bile ducts, whereas secondary stones develop in the gallbladder and subsequently fall into the CBD. In the United States more than 85% of all bile duct stones are secondary. Primary duct stones typically occur in patients with benign biliary strictures, sclerosing cholangitis, choledochal cyst disease, or sphincter of Oddi dysfunction. These conditions are associated with bile stasis, which promotes the overgrowth of bacteria in bile with subsequent deconjugation of bilirubin and the breakdown of biliary lipids, resulting in the formation of brown pigment stones. Secondary bile duct stones have a composition similar to gallbladder stones. Approximately 75% are cholesterol stones, and 25% are black pigment stones. The classification of CBD stones into primary or secondary is of therapeutic importance because primary stones require removal of the stones and a drainage procedure (choledochenterostomy or sphincteroplasty), whereas secondary stones can be treated by removal of the stones and cholecystectomy.

Clinical Presentation

Common duct stones are often asymptomatic and only discovered during cholangiography at the time of cholecystectomy. CBD stones are present in 8% to 15% of patients with symptomatic gallstones. The incidence varies with age and is less than 5% in younger patients and more than 20% in older patients with gallstones. Patients with symptomatic choledocholithiasis will present with biliary colic, extrahepatic biliary obstruction, cholangitis, or pancreatitis. Clinical features suspicious for biliary obstruction caused by CBD stones include biliary colic, jaundice, lightening of the stools, and darkening of the urine. Typically, the pain and jaundice associated with CBD stones are more intermittent and transient than when the biliary obstruction is caused by a malignancy. In addition, fever and chills may be present in patients with choledocholithiasis and cholangitis. Gallstone pancreatitis can develop from the obstruction of the ampulla of Vater by common duct stones. CBD stones are responsible for up to 50% of all cases of pancreatitis. Most patients with gallstone pancreatitis experience a mild self-limited attack from which they recover

within a few days; however, some patients will progress to develop severe pancreatitis with peripancreatic necrosis, infection, or pseudocyst formation.

Predictors of Common Bile Duct Stones

No single clinical variable is completely accurate in predicting the presence of choledocholithiasis. Therefore, the results of a detailed history and physical examination, laboratory evaluations, and diagnostic imaging tests must be taken together when assessing the likelihood that a patient has CBD stones. Serum liver function tests (bilirubin, alkaline phosphatase, and transaminases) can be useful in predicting common duct stones. If any one value of the liver profile is elevated, the risk for CBD stones approaches 20%. With two elevated values the risk increases to nearly 40%, and with three or more elevated values the risk for CBD stones is nearly 50%. However, between 5% and 7% of patients with no liver function abnormalities have CBD stones identified by cholangiography at the time of cholecystectomy. A recent meta-analysis has shown the presence of cholangitis, CBD stones identified on ultrasound, and jaundice to be the strongest indicators of CBD stones.²⁹ A patient with any one of these indicators has at least 10 times the risk of having CBD stones compared with a patient without the risk factor (Table 60.5).

Diagnostic Studies

Ultrasonography. Ultrasound (US) is very sensitive for the diagnosis of gallstones within the gallbladder. Unfortunately, the sensitivity of US for the detection of CBD stones is only 15% to 30%. Ultrasound can identify CBD dilation, which can suggest choledocholithiasis. If the extrahepatic bile duct diameter is less than 3 mm, CBD stones are exceedingly rare, whereas a diameter greater than 10 mm in a jaundiced patient predicts CBD stones in more than 90% of cases. Ultrasound successfully identifies the presence of CBD stones in only 70% of patients because the distal end of the bile duct is frequently obscured by duodenal or colonic gas.

Magnetic Resonance Imaging. Magnetic resonance cholangiopancreatography (MRCP) is another noninvasive means of imaging the biliary tract (Fig. 60.15). Several studies have shown that MRCP can diagnose CBD stones with a sensitivity

TABLE 60.5

DIAGNOSIS

PREDICTIVE VALUES OF PREOPERATIVE INDICATORS OF COMMON BILE DUCT STONES

■ INDICATOR	■ POSITIVE LIKELIHOOD RATIO	■ NEGATIVE LIKELIHOOD RATIO	■ SENSITIVITY	■ SPECIFICITY
Cholangitis	18.3	0.93	0.11	0.99
Common bile duct stones on ultrasound	13.6	0.70	0.38	1.00
Preoperative jaundice	10.1	0.69	0.36	0.97
Elevated bilirubin	4.8	0.77	0.69	0.88
Elevated alkaline phosphatase	2.6	0.65	0.57	0.86
Pancreatitis	2.1	0.96	0.10	0.95
Cholecystitis	1.6	0.94	0.50	0.76
Amylase	1.5	0.99	0.11	0.95

FIGURE 60.15. Magnetic resonance cholangiogram showing common bile duct stones (arrows).

of 90%, a specificity of 100%, and an overall diagnostic accuracy of 97%. The main advantage of MRCP is that it allows for the direct imaging of the biliary tract without the need for contrast or an invasive procedure. Disadvantages include its relatively high cost and lack of therapeutic capacity. Magnetic resonance cholangiography has been used to screen patients at low and moderate risk of having common duct stones prior to endoscopic cholangiography. A normal magnetic resonance cholangiogram can avoid the need for an invasive endoscopic cholangiogram. MRCP has become more popular as costs have reduced and surgeons have become more skilled with laparoscopic techniques for managing CBD stones.

Endoscopic Ultrasound. Endoscopic ultrasound (EUS) is a semi-invasive test that can be performed with a very low rate of complications (<0.1%).³⁰ The sensitivity and specificity for the diagnosis of CBD stones by EUS ranges from 92% to 100% and 95% to 100%, respectively. The negative predictive value for EUS is more than 97%.³¹ Therefore, when EUS is

FIGURE 60.16. Endoscopic retrograde cholangiogram showing common bile duct stones.

negative for common duct stones, ERCP or intraoperative cholangiography can be avoided.

Preoperative Cholangiography. Endoscopic cholangiography is the “gold standard” for the diagnosis of CBD stones. Both endoscopic retrograde cholangiography (ERC) and percutaneous transhepatic cholangiography (PTC) techniques can be used to directly visualize the biliary tree. A comparison of endoscopic retrograde cholangiography and percutaneous transhepatic cholangiography techniques is noted in Table 60.6. Endoscopic cholangiography (Fig. 60.16) has the advantage of providing a therapeutic option at the time CBD stones are identified and is therefore the preferred approach for patients with suspected CBD stones. Skilled endoscopists can successfully cannulate the CBD in approximately 90% to 95% of

COMPARISON OF PERCUTANEOUS TRANSHEPATIC CHOLANGIOGRAPHY AND ENDOSCOPIC RETROGRADE CHOLANGIOGRAPHY

■ CRITERION	■ TRANSHEPATIC CHOLANGIOGRAPHY	■ ENDOSCOPIC CHOLANGIOGRAPHY
Success rate	>90% with dilated ducts, 70% with nondilated ducts	80%–90% with either dilated or nondilated ducts
Identification of cause of obstruction	90%–100%	75%–90%
Complications	5% (range, 3%–10%)	5% (range, 2%–7%)
Mortality	0.2%–0.9%	0.1%–0.2%
Expense	Less	More
Skill required	Less	More
Patient selection	Proximal lesions, altered gastroduodenal anatomy, failed endoscopic cholangiography	Distal lesions, pancreatic pathology, coagulopathy, ascites, failed transhepatic cholangiography

patients. Complications of diagnostic cholangiography include pancreatitis and cholangitis and occur in up to 5% of patients. ERC may be unsuccessful in patients with previous gastric surgery (Billroth II reconstruction), periampullary diverticula, or tortuous biliary ducts. Percutaneous transhepatic cholangiography may be used to image the bile ducts if ERC is unsuccessful.

Intraoperative Cholangiography. Intraoperative cholangiography (IOC) also can be successfully accomplished in more than 95% of cases. The cholangiogram should be carefully evaluated for filling defects within the ducts, presence of contrast in the duodenum, and the intrahepatic biliary anatomy. Debate continues over the need to perform routine intraoperative cholangiography at the time of cholecystectomy. Advocates of routine IOC argue that asymptomatic CBD stones can be identified and biliary injuries prevented by performing routine IOC. Critics of this approach suggest that the incidence of retained stones is no greater when cholangiography is performed selectively based on clinical and laboratory criteria. The indications for performing cholangiography during cholecystectomy include (a) a dilated CBD, (b) a wide cystic duct, (c) palpable CBD stones, (d) elevated serum liver function tests or bilirubin, and (e) a history of pancreatitis. If these criteria are strictly followed, approximately 30% of patients will require IOC at the time of cholecystectomy. IOC can identify the size, number, and location of CBD stones in addition to defining biliary anatomy. This information is critical in choosing the most appropriate treatment for CBD stones.

Intraoperative Ultrasonography. Intraoperative ultrasonography also can be used to identify CBD stones at the time of cholecystectomy. In experienced hands, intraoperative ultrasonography has been shown to be comparable to intraop-

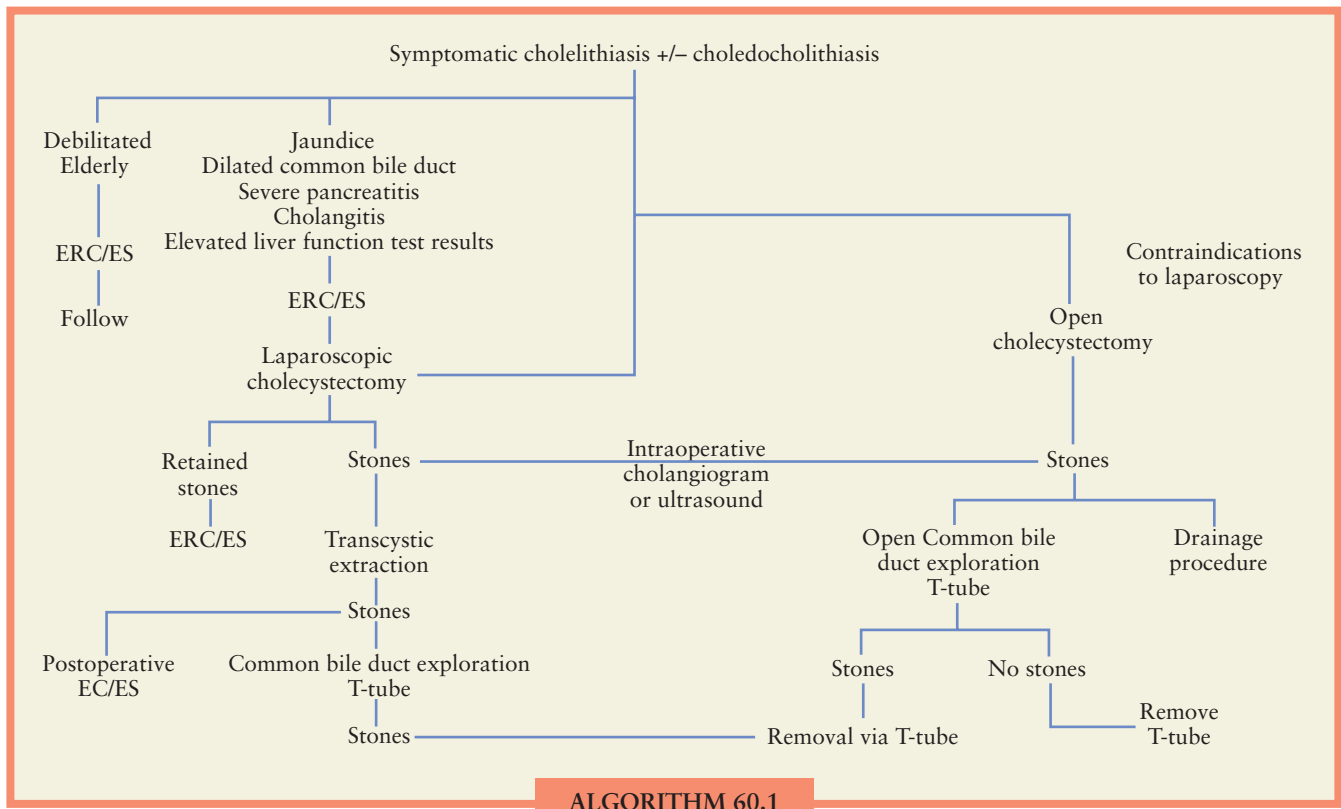

erative cholangiography for the diagnosis of CBD stones. Laparoscopic ultrasonography is performed with a high frequency (7.5- to 10-MHz) probe, and the bile duct is imaged in the transverse and longitudinal planes. The distal bile duct can be visualized in more than 95% of cases.

The choice of radiologic studies used to evaluate a patient with suspected choledocholithiasis should be based on the probability of this diagnosis. Patients at highest risk for choledocholithiasis should undergo endoscopic cholangiography. Patients at intermediate risk may be screened with magnetic resonance cholangiography or endoscopic ultrasound and proceed to laparoscopic cholecystectomy if no stones are identified. Those patients at low risk of harboring common duct stones may be evaluated with intraoperative cholangiography at the time of laparoscopic cholecystectomy with laparoscopic CBD exploration or postoperative endoscopic stone extraction reserved for the few patients with a positive study.³²

Management

Currently, several options are available to the surgeon for the treatment of CBD stones. In choosing the most appropriate approach for an individual patient, factors such as the local endoscopic expertise, the surgeon's laparoscopic skill, and the patient's clinical condition must be considered. A potential approach to the management of CBD stones is shown in Algorithm 60.1.

- 10 Endoscopic.** ERC with endoscopic sphincterotomy permits CBD stones to be removed without the need for conventional surgery. Stones can be successfully removed from the CBD in 85% to 95% of cases. The endoscopic approach is particularly useful for patients prior to cholecystectomy in whom a high suspicion exists for CBD calculi, particularly if laparoscopic

ALGORITHM 60.1. Algorithm for the management of common bile duct stones.

CBD exploration is not available. Endoscopic clearance of stones from the CBD precholecystectomy can avoid the need for an open operation. Furthermore, if endoscopic stone extraction is not possible because of multiple gallstones, intrahepatic stones, large gallstones, impacted stones, duodenal diverticula, prior gastrectomy, or bile duct stricture, this information is known before cholecystectomy, and an open CBD exploration or drainage procedure can be performed. After sphincterotomy, most stones smaller than 1 cm in diameter pass spontaneously. A balloon catheter or stone basket also can be used to retrieve stones if needed. If endoscopic clearance is incomplete, an endoscopic stent can be placed into the CBD to maintain drainage and prevent cholangitis.

Endoscopic sphincterotomy and stone extraction is well tolerated in most patients. Complications occur in 5% to 8% of patients and include cholangitis, pancreatitis, perforation, and bleeding. The overall mortality rate is 0.2% to 0.5%. Complete clearance of all common duct stones is achieved endoscopically in 71% to 75% of patients at the first procedure and in 84% to 95% of patients after multiple endoscopic procedures.³³

Preoperative ERC plus endoscopic sphincterotomy is the preferred management option for CBD stones in several conditions. In the setting of acute suppurative cholangitis, morbidity and mortality are significantly decreased if preoperative biliary decompression and stone removal are accomplished before cholecystectomy. Patients with severe gallstone pancreatitis or a significant deterioration of their clinical condition also have been shown to benefit from early ERC and stone clearance. Cholecystectomy can then be performed after the pancreatitis has resolved. In patients with a dilated CBD (>8 mm) on ultrasound and jaundice, an ERC also should be performed to rule out a malignancy or biliary stricture that would alter the surgical management. In patients with a high operative risk, ERC plus endoscopic sphincterotomy can be performed to remove CBD stones and the gallbladder left in place.

Following endoscopic sphincterotomy and stone extraction, patients with a stone-filled gallbladder remain at high risk of developing future biliary symptoms. A prospective randomized trial demonstrated a significantly greater incidence of recurrent biliary symptoms among patients managed with a wait-and-see approach versus laparoscopic cholecystectomy (47% vs. 2%, $p < 0.0001$) following endoscopic stone extrac-

tion. A large percentage (37%) of patients managed expectantly later required cholecystectomy.³⁴

Laparoscopic. Laparoscopic exploration of the CBD for choledocholithiasis enables appropriate patients to undergo complete management of their calculous biliary tract disease with one invasive procedure. This approach is the most cost effective and should become the preferred option as surgeons' laparoscopic skills improve.³⁵ The laparoscopic approach is ideal for patients with CBD stones identified during intraoperative cholangiography or ultrasound or in patients with suspected choledocholithiasis managed at centers where laparoscopic CBD exploration is routinely performed. Intraoperative cholangiography is accomplished via the cystic duct prior to duct exploration.

The two approaches for laparoscopic bile duct exploration are laparoscopic transcystic common bile duct exploration (LTCBDE) or laparoscopic choledochotomy (Table 60.7). The indications for transcystic duct exploration are filling defects noted on cholangiography (CBD stones), stones less than 9 mm in diameter, stones below the cystic duct entrance to the bile duct, and fewer than six stones. Contraindications to LTCBDE are a small friable cystic duct, more than eight stones in the CBD, common hepatic duct stones, and stones larger than 1 cm. Laparoscopic choledochotomy can be performed if LTCBDE fails or is contraindicated, if stones are present above the cystic duct, or when multiple stones are present. The only contraindication to laparoscopic choledochotomy is a small common duct (<6 mm) that might be narrowed during its closure.

Laparoscopic Transcystic Common Bile Duct Exploration. The technique of LTCBDE involves the blunt dissection of the cystic duct down to its junction with the CBD. A cystic ductotomy is then made and a guide wire inserted into the bile duct. A cholangiocatheter can then be advanced over the guide wire into the bile duct and saline irrigated through the catheter in an attempt to flush small stones out of the bile duct. If the stones in the CBD are larger than the lumen of the cystic duct, the cystic duct can be dilated with a balloon catheter. Stone retrieval baskets can be inserted over the guide wire and stones extracted under fluoroscopic guidance (Fig. 60.17). Flexible choledochoscopy via the cystic duct also can be performed and stones extracted under direct vision. Success rates

TABLE 60.7

TREATMENT

FACTORS IN LAPAROSCOPIC TRANSCYSTIC COMMON BILE DUCT EXPLORATION VERSUS LAPAROSCOPIC CHOLEDOCHOTOMY

	■ TRANSCYSTIC	■ CHOLEDOCHOTOMY
Stone characteristics		
Number	<8	Any
Size	>9 mm	Any
Location	Distal to cystic duct	Entire duct
Bile duct size	Any	>6 mm
Drain	Optional cystic duct tube	T-tube
Contraindications	Friable cystic duct Intrahepatic stones Multiple large stones	Small-diameter duct Inability to suture laparoscopically
Advantages	No T-tube Short hospital stay	T-tube for postoperative access
Adapted from Phillips EH, Korman JE. Laparoscopic management of common bile duct stones. In: Cameron JL, ed. <i>Current Surgical Therapy</i> , 6th ed. St. Louis, MO: Mosby; 1998.		

FIGURE 60.17. Laparoscopic transcystic bile duct exploration.

greater than 95% have been reported for bile duct clearance using choledochoscopy. To document stone clearance, a completion cholangiogram should be performed. A cystic duct drainage tube can be left in place if findings on the cholangiogram are equivocal. This tube can be used postoperatively for cholangiography and radiographic treatment of retained stones if necessary.

Laparoscopic Choledochotomy. Laparoscopic choledochotomy is another excellent approach to CBD stones when the CBD diameter is 6 mm or greater. The anterior wall of the CBD is bluntly dissected and a longitudinal choledochotomy made in the anterior wall below the cystic duct. The choledochotomy should be made as long as the diameter of the largest stone. Two stay sutures can be placed in the common duct and used to tent up the anterior wall to facilitate the incision. A larger choledochoscope (3.3 mm, 2.4-mm working channel) can then be placed into the bile duct and stones extracted with baskets or balloon catheters. The choledochotomy is then closed over a T-tube with a 4–0 absorbable suture.

Advantages of laparoscopic choledochotomy over LTCBDE include the ability to remove larger stones (>1 cm), to remove stones from the proximal hepatic ducts, to remove multiple stones, and to use biliary lithotripsy to fragment impacted stones. The disadvantages of laparoscopic choledochotomy are that it requires a T-tube and considerable laparoscopic suturing skill to close the choledochotomy.

Clearance of all CBD stones is achieved in 75% to 95% of patients with laparoscopic CBD exploration.³⁵ The morbidity and mortality of laparoscopic CBD exploration are similar to laparoscopic cholecystectomy alone. In a prospective randomized trial comparing laparoscopic CBD exploration at the time of laparoscopic cholecystectomy with postoperative endoscopic stone extraction following laparoscopic cholecystectomy, the complication rate and retained stone rate were similar between the two groups. The median hospital stay was significantly shorter for patients managed with the single invasive procedure (1 day vs. 3.5 days).

Open Common Bile Duct Exploration. Open CBD exploration is performed much less frequently with the increased use of endoscopic, percutaneous, and laparoscopic techniques to remove CBD stones. Occasionally, when these methods fail, are not available, or are not possible because of prior surgery, or when open operation is otherwise required, open CBD

exploration becomes necessary. The technique will be described briefly because open CBD exploration is not commonly performed in the era of laparoscopic cholecystectomy. The first step is to perform a full Kocher maneuver mobilizing the duodenum so that a hand can be placed behind the head of the pancreas and the distal CBD palpated. Any impacted stones may be milked more proximally. The supraduodenal bile duct is then exposed and two stay sutures placed in the CBD just below the cystic duct. The anterior wall of the bile duct is then elevated with the stay sutures and a longitudinal choledochotomy made. The bile duct then can be explored for stones. Rigid instruments should not be used to extract stones because they can injure the delicate ductal epithelium. A soft rubber irrigating catheter can be used to gently flush out any stones or debris. Balloon-tipped catheters then can be passed proximally and distally into the ducts to retrieve stones. Adequate clearance of the duct should be confirmed visually with flexible choledochoscopy. Remaining stones can be removed by irrigation or the use of instruments such as stone forceps, wire baskets, or balloon catheters. A T-tube should be placed in the bile duct and the choledochotomy closed with 4–0 absorbable suture. Completion cholangiography is performed before closing the abdomen to rule out the presence of retained stones or a bile leak around the T-tube. Postoperatively, a T-tube cholangiogram is performed 3 to 7 days after the exploration. If the cholangiogram is normal, the tube can be clamped and the tube pulled 3 to 6 weeks later. If retained stones are detected, the tract is allowed to mature, and percutaneous extraction can be performed by a radiologist in 4 to 6 weeks. Open CBD exploration can be accomplished with almost no mortality in patients younger than age 60 years but can have a mortality of up to 4% in septic patients.

Drainage Procedures. Patients with an impacted stone at the ampulla that cannot be removed with a CBD exploration or with multiple stones in a nondilated duct may require a transduodenal sphincteroplasty. A sphincteroplasty also is indicated in the presence of an ampullary stenosis or a choledochocoele. The first step in a sphincteroplasty is to perform a Kocher maneuver. A small longitudinal duodenotomy is made over the ampulla and two stay sutures placed on each side of the ampulla to elevate it. A small incision is made at the 11-o'clock position in the sphincter taking care to avoid the pancreatic duct, which is usually found at the 5-o'clock position. The sphincterotomy is extended through the sphincter (approximately 1.5 cm) and the impacted stone removed. The bile duct and duodenal mucosa are then reapproximated with interrupted 4–0 absorbable sutures. The duodenotomy should be closed transversely to prevent narrowing of the lumen.

Patients with grossly dilated bile ducts (>2 cm), multiple stones (>5), intrahepatic stones, primary duct stones, or a distal biliary stricture should be considered for a biliary drainage procedure. The two options are a choledochoduodenostomy or a Roux-en-Y choledochojejunostomy. The choledochoduodenostomy can be performed in either a side-to-side or an end-to-side fashion. Advantages of a choledochoduodenostomy are that it can be performed rapidly, it requires only one anastomosis, and the bile duct still can be accessed endoscopically. However, a side-to-side anastomosis leaves the distal CBD in continuity and can lead to the “sump syndrome.” In this situation, food debris from the duodenum can enter the distal limb of the duct and obstruct the anastomosis or the pancreatic duct orifice, leading to cholangitis or pancreatitis. Roux-en-Y hepaticojejunostomy or choledochojejunostomy also is an excellent option for biliary drainage. This operation is performed by dividing the hepatic or common duct and doing an end-to-end anastomosis to a 60-cm Roux limb. Development of the sump syndrome is not a concern because a hepaticojejunostomy or choledochojejunostomy is completely diverting.

TABLE 60.8 RESULTS**SUMMARY OF TREATMENT AND OUTCOMES FOR INTRAHEPATIC STONE DISEASE AT THE JOHNS HOPKINS HOSPITAL**

Patient, <i>n</i>	54
Percutaneous treatment only	26% of patients
Surgical treatment	74% of patients
Postoperative percutaneous treatment	33% of patients
Mean follow-up	60 mo
Successful stone clearance	94% of patients
Symptom-free state	87% of patients
Recurrent stones or stricture	20% of patients
Adapted with permission from Pitt HA, Venbrux AC, Coleman JA, et al. Intrahepatic stones: the transhepatic team approach. <i>Ann Surg</i> 1994;219:527.	

Intrahepatic Stones

Intrahepatic stones are relatively uncommon in Western countries. These stones are more prevalent in Asia and represent a difficult management problem. Intrahepatic stones are primarily brown pigment stones. They typically occur in association with diseases characterized by prolonged partial bile duct obstruction, such as sclerosing cholangitis, benign and malignant biliary strictures, choledochal cysts, and biliary parasites.

Cholangiography, either endoscopic or percutaneous, is the most valuable technique in the evaluation of patients with intrahepatic stones. The transhepatic percutaneous approach is preferable in most patients because it allows for direct access to the intrahepatic bile ducts for therapeutic interventions. Transhepatic biliary drainage catheters can be inserted and gradually upsized to a 16- to 20-French size. The tract is then allowed to mature for 5 to 6 weeks, and stones are removed by using steerable stone retrieval baskets under fluoroscopic guidance, or with percutaneous choledochoscopy.

Although some patients with intrahepatic stone disease can be managed nonoperatively, many patients will require surgical intervention. A Roux-en-Y hepaticojejunostomy is usually constructed and intraoperative choledochoscopy used to clear the bile ducts of stones. Large-bore transhepatic stents can be placed intraoperatively to provide access to the biliary tree for percutaneous stone extraction or the treatment of strictures postoperatively. Using this approach, a stone clearance rate of greater than 90% can be expected (Table 60.8).³⁶ Another option for management of intrahepatic stones is the creation of a hepaticocutaneous jejunostomy. This technique involves creating a Roux-en-Y hepaticojejunostomy with a longer than usual Roux limb and extending the Roux limb beyond the anastomosis up to the anterior abdominal wall. The limb is then marked with metal wire or clips, which allows percutaneous access to the biliary system if needed. If the intrahepatic stone disease is isolated to a single lobe or segment of liver and is associated with significant intrahepatic biliary strictures or atrophy, a hepatic resection may be indicated to treat the stone disease.

CHAPTER 61 ■ BILIARY INJURIES AND STRICTURES AND SCLEROSING CHOLANGITIS

KEITH D. LILLEMÖE

KEY POINTS

- 1 Most bile duct injuries or strictures currently occur in association with laparoscopic cholecystectomy, with an overall incidence of 0.3% to 0.7%.
- 2 Recognition of a bile duct injury during laparoscopic cholecystectomy is uncommon (<30% of cases), but if recognized, repair as either an end-to-end duct-to-duct anastomosis in very selected cases or hepaticojejunostomy should be performed.
- 3 Cholangiography, usually performed by a percutaneous transhepatic route, should be performed in all cases to define the proximal biliary anatomy needed for reconstruction and to allow placement of biliary catheters to control the ongoing bile leak.
- 4 Patients with biliary injuries most commonly present in the early postoperative course, usually with bile leakage. Despite recognition of an ongoing bile leak, urgent return to the operating room should be avoided.
- 5 The repair of a bile duct injury recognized in the postoperative period requires a hepaticojejunostomy in almost all cases and should be performed with transanastomotic biliary stents.
- 6 A successful result following repair of a bile duct injury can be expected in 80% to 90% of patients. Return to a normal quality of life is also expected. In the modern era, death associated with either bile duct injury or the operative repair is uncommon, occurring in less than 2% of patients.
- 7 Percutaneous or balloon dilatation of biliary strictures can lead to successful outcomes in selective patients, although the long-term results generally favor surgical reconstruction.
- 8 Primary sclerosing cholangitis is an autoimmune disease characterized by intrahepatic and extrahepatic inflammatory strictures of the bile ducts. Patients are at risk for the development of cholangiocarcinoma and/or end-stage liver disease. There is no known specific effective medical therapy for primary sclerosing cholangitis. Primary sclerosing cholangitis has become one of the most common indications for liver transplantation.
- 9 Bile duct strictures associated with alcoholic chronic pancreatitis are best managed by biliary bypass.

Biliary injuries and strictures are among the most difficult challenges that a surgeon faces. Although numerous technologic developments have facilitated diagnosis and management, bile duct injuries and strictures remain a significant clinical problem. If they go unrecognized or are managed improperly, life-threatening early complications such as sepsis and multisystem organ failure or late implications of biliary cirrhosis, portal hypertension, and cholangitis can develop. To avoid these complications, virtually every patient with a bile duct stricture should undergo evaluation and treatment with the goal of relieving the obstruction to bile flow and its associated hepatic injury. Finally, the occurrence of a major bile duct injury during an elective cholecystectomy remains one of the most common indications for charges of medical practice in the United States.

Benign bile duct strictures can have numerous causes (Table 61.1). Most biliary strictures occur after primary operations on the gallbladder or biliary tree. With the introduction of laparoscopic cholecystectomy, bile duct injuries and associated strictures have been seen with increased frequency. Operative injury to the bile ducts can also occur during nonbiliary operations on the gallbladder or biliary tree or as a result of external penetrating or blunt abdominal trauma. Inflammatory conditions and fibrosis caused by chronic pancreatitis, gallstones in the gallbladder or the bile duct, stenosis of the sphincter of Oddi, or biliary tract infections can also cause benign bile duct strictures. Finally, primary sclerosing cholangitis, a rare disease of unknown cause, can result in multiple strictures of the intrahepatic and extrahepatic bile ducts. This

chapter focuses primarily on postoperative bile duct strictures and primary sclerosing cholangitis.

POSTOPERATIVE BILE DUCT STRICTURES

Pathogenesis

Most benign bile duct strictures result from operations in or near the right upper quadrant. More than 80% of strictures occur after injury to the bile ducts during cholecystectomy. The exact incidence of bile duct injury is unknown because

- 1 many cases may go unreported in the literature. Data suggest that the incidence of bile duct injury during open cholecystectomy is 1 in 500 to 1,000 cases. The incidence of bile duct injury during laparoscopic cholecystectomy is clearly higher. Although a wide range in the incidence of injury can be found in reported series, the most accurate data most likely come from surveys encompassing thousands of patients. These reports reflect the results from a large number of surgeons in both community and teaching hospitals. The results of such series suggest an incidence of bile duct injury during laparoscopic cholecystectomy ranging from 0.3% to 0.7%.¹ Furthermore, the incidence of bile duct injury associated with laparoscopic cholecystectomy does not appear to have diminished in more recent surveys, suggesting that the previously observed increase is not simply the result of a learning curve associated

with the laparoscopic technique. Finally, due to the high frequency of laparoscopic cholecystectomy, it is estimated that one in every two or three surgeons will create a bile duct injury during his or her career.

A number of factors are associated with bile duct injury during either open or laparoscopic cholecystectomy, including acute or chronic inflammation, inadequate exposure, patient obesity, and failure to identify structures before clamping, ligating, or dividing them. More specific causes of bile duct injury also exist. Bleeding from the cystic or hepatic arteries can lead to bile duct injury during attempts to gain hemostasis. The generous application of Ligaclips at either open or laparoscopic cholecystectomy to hilar areas not well visualized can result in placing a clip on or across a bile duct, with resultant injury (Fig. 61.1). Failure to recognize congenital anatomic anomalies of the bile ducts, such as insertion of the right hepatic duct into the cystic duct or a long common wall between the cystic duct and the common bile duct, can also lead to injury (Fig. 61.2).

A number of technical factors are associated with laparoscopic cholecystectomy that can also increase the risk of bile duct injury compared with the open procedure. These factors include the use of an end-viewing laparoscope, which alters the surgeon's perspective of the operative field. Excessive cephalad retraction of the gallbladder fundus can cause the cystic duct and common bile duct to become aligned in the same plane. This distortion often results in the classic laparoscopic injury, in which the common bile duct is mistaken for the cystic duct and clipped and divided (Fig. 61.3).² The role of intraoperative cholangiography (IOC) in preventing bile duct injury during laparoscopic cholecystectomy is controversial. Individual series have failed to demonstrate that either performing routine or selective IOC affects the incidence of bile duct injury. However, a retrospective nationwide cohort analysis of Medicare patients undergoing laparoscopic cholecystectomy between 1992 and 1999 demonstrated that common bile duct injury occurred in 0.39% of patients in which IOC was performed versus 0.58% in patients not undergoing IOC (unadjusted relative risk, 1.49; 95% confidence interval

FIGURE 61.1. Percutaneous transhepatic cholangiogram in a patient with a bile duct stricture secondary to iatrogenic injury during cholecystectomy. Numerous surgical clips can be seen in the area of the stricture. (Reproduced with permission from Lillemoe KD, Pitt HA, Cameron JL. Postoperative bile duct strictures. *Surg Clin North Am* 1990;70:1356.)

FIGURE 61.2. Operative cholangiogram demonstrating a right lobe segmental bile duct entering the cystic duct (arrow). Division of the cystic duct proximal to this insertion can result in a bile leak or obstruction of bile flow from a significant segment of the liver.

FIGURE 61.3. Classic laparoscopic bile duct injury. The common bile duct is mistaken for the cystic duct and transected. A variable extent of the extrahepatic biliary tree is resected with the gallbladder. The right hepatic artery, in background, is also often injured. (Adapted from Branum G, Schmidt C, Baillie J, et al. Management of major biliary complications after laparoscopic cholecystectomy. *Ann Surg* 1993;217:532.)

1.42–1.57).³ Furthermore, the proper interpretation of IOC can minimize the extent of injury. Nevertheless, only 27% of surgeons in the United States perform IOC routinely.⁴ Finally, ample evidence exists to support the conclusion that the experience of the surgeon in performing laparoscopic cholecystectomy can be correlated with the risk of bile duct injury.

In recent years there has been a growing understanding of surgeon cognitive factors associated with bile duct injury during laparoscopic cholecystectomy. An analysis examining 252 biliary injuries during laparoscopic cholecystectomy using human error factor and cognitive science techniques found that 97% of injuries were caused by visual-perceptual illusion or inadequate visualization.⁵ Further work from the same group has determined a major explanation for the surgeon's frequent inability to recognize bile duct injury. These bile duct injuries appear to be associated with confirmation bias, which is a propensity to seek cues to confirm a belief and to discount cues that might discount the belief. Although cognitive factors are important for the understanding of the psychological issues associated with bile duct injuries, surgeons must continue to have the appropriate corrective mechanisms in place to minimize the chance of these injuries, including knowledge of anatomy, typical mechanisms of injury, and an appropriate level of suspicion and logic. An example of such a corrective mechanism is the operative technique of laparoscopic cholecystectomy, which defines the "critical view of safety," which helps prevent misidentification and injury of the major bile ducts.⁶

The importance of ischemia of the bile duct in the formation of postoperative strictures has been emphasized. Injury to the hepatic artery at the time of biliary injury during laparoscopic cholecystectomy has been recognized at an increased incidence, as high as 50%, when investigated at the time of presentation.⁷ The presence of an arterial injury, however, does not appear to affect either early or late outcomes. A more clinically important cause of ischemia can be unnecessary dissection around the bile duct during cholecystectomy or bile duct anastomosis, which can divide or injure the major arteries of the bile duct that run in the 3-o'clock and 9-o'clock positions.

Another important factor contributing to the formation of biliary strictures is the intense connective tissue response with

fibrosis and scarring that can occur after bile duct injury. Experimental studies of bile duct ligation in a canine model have demonstrated immediate and sustained elevation of bile duct pressure and progressive increase in bile duct diameter. Histologic changes at 1 month after ligation have shown that the bile duct wall is thickened, with a reduction of mucosal folds and loss of surface microvilli, associated with a well-defined epithelial degeneration. Biochemical analysis of connective tissue response to ligation showed that collagen synthesis and proline hydroxylase activity is increased within 2 weeks in the obstructed bile duct and is sustained throughout the period of observation. Finally, a marked local inflammatory response can develop in the adjacent tissue in association with bile leakage, which occurs with many bile duct injuries. This inflammation can be further intensified in the face of infection. This inflammation results in fibrosis and scarring in the periductal tissue, further contributing to stricture formation. These factors can be of major importance in bile duct injuries during laparoscopic cholecystectomy, which are frequently associated with bile leaks.

After cholecystectomy and common bile duct exploration, the two most common operations associated with bile duct injury are gastrectomy and hepatic resection. The most common situation resulting in bile duct injury during gastrectomy involves dissection of the pyloric region and the first portion of the duodenum in the face of inflammation from peptic ulcer disease. The injury occurs during mobilization of the duodenum either for creation of a Billroth I gastroduodenostomy or for closure of the duodenal stump. Biliary injury during liver resection is most likely to occur during dissection of the hepatic hilum.

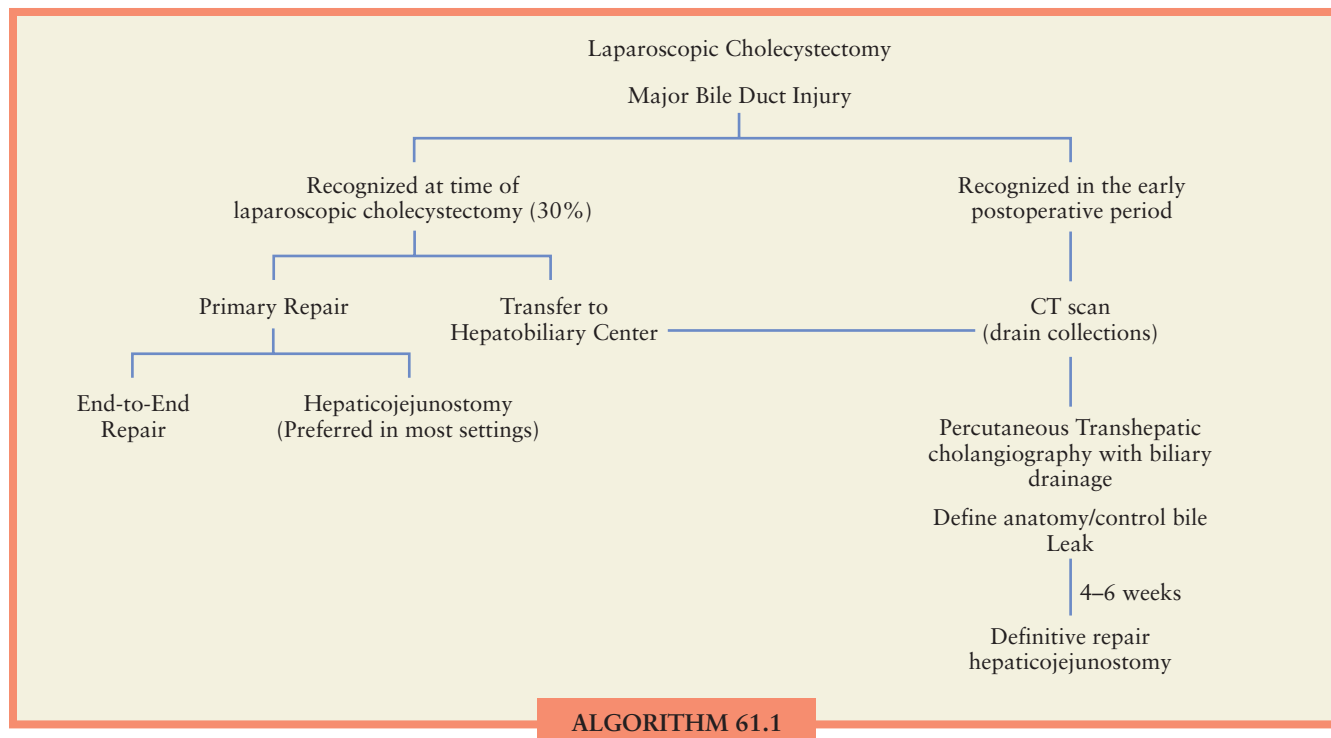

In addition to iatrogenic bile duct injury occurring during cholecystectomy or other operations, bile duct strictures can also occur at biliary anastomoses. Such strictures can occur at a biliary-enteric anastomosis performed for reconstruction after resection for benign or malignant disease of the pancreaticobiliary system, or after end-to-end bile duct anastomosis performed for hepatic transplantation or for repair of traumatic injury. Ischemia of the anastomosis caused by excessive skeletonization of the duct in preparation for the anastomosis is an important factor in many such strictures.

Unfortunately, the recurrence of bile duct strictures after an initial attempt at repair is not uncommon and can also account for a number of anastomotic strictures.^{8,9} A number of other factors have been evaluated in patients who have a recurrent bile duct stricture, including the location of the stricture, the length of follow-up, the influence of previous operations, the type of operation performed, the type of sutures used, and the use and duration of postoperative stenting.⁸ Previous attempts at repair, performance of a procedure other than choledochojunostomy or hepaticojejunostomy, and stricture location higher in the biliary tree appear to be associated with a higher incidence of recurrent stricture. Finally, long-term follow-up of a bile duct anastomosis is important because strictures can develop years after the original anastomosis.

Clinical Presentation

Most patients with biliary injuries present early after their initial operation (Algorithm 61.1). After open cholecystectomy, only approximately 10% of postoperative strictures are actually suspected within the first week, but nearly 70% are diagnosed within the first 6 months, and more than 80% are diagnosed within 1 year of surgery. In series reporting bile duct injuries during laparoscopic cholecystectomy, the injury is usually recognized either during the procedure (25% to 30%) or, more commonly, in the early postoperative period.

Patients suspected of having a postoperative bile duct injury within days to weeks of initial operation usually present in one of two ways. One presentation is the progressive elevation of

ALGORITHM 61.1. Algorithm for diagnosis and management of bile duct injury associated with laparoscopic cholecystectomy.

liver function test results, particularly total bilirubin and alkaline phosphatase levels. These changes can often be seen as early as the second or third postoperative day. The second mode of early presentation is with leakage of bile from the injured bile duct. This presentation appears to occur most often in patients presenting with bile duct injuries after laparoscopic cholecystectomy. Bilious drainage from operatively placed drains or through the wound after cholecystectomy is abnormal and represents some form of biliary injury. In patients without drains (including patients in whom the drains have been removed), the bile can leak freely into the peritoneal cavity or it can loculate as a collection. Free accumulation of bile into the peritoneal cavity results in either biliary ascites or bile peritonitis. Similarly, a loculated bile collection can result in sterile biloma (Fig. 61.4) or in an infected subhepatic or subdiaphragmatic abscess.

Patients with postoperative bile duct strictures who present months to years after the initial operation frequently have evidence of cholangitis. The episodes of cholangitis are often mild and respond to antibiotic therapy. Repetitive episodes usually occur before the definitive diagnosis. Less commonly, patients may present with painless jaundice and no evidence of sepsis. Finally, patients with markedly delayed diagnoses may present with advanced biliary cirrhosis and its complications.

Laboratory Investigation

Liver function tests usually show evidence of cholestasis. In patients with bile leakage, the bilirubin can be normal or minimally elevated because of absorption from the peritoneal cavity. When elevated, serum bilirubin usually ranges from 2 to 6 mg/dL, unless secondary biliary cirrhosis has developed. Serum alkaline phosphatase is usually elevated. Serum aminotransferase levels can be normal or minimally elevated except during episodes of cholangitis. If advanced liver disease exists, hepatic synthetic function can be impaired, with lowered serum albumin and a prolongation of prothrombin time.

Serum electrolytes and complete blood count are typically normal unless there is associated biliary sepsis.

Radiologic Examination

The imaging techniques of abdominal ultrasound and computed tomography (CT) play an important initial role in the evaluation of patients with benign postoperative biliary strictures. In patients who present in the early postoperative period with evidence of a bile leak or biliary sepsis, these studies are useful to rule out the presence of intra-abdominal collections

FIGURE 61.4. Large bile duct collection (biloma; arrow) occurring after bile duct injury. (Reproduced with permission from Lillemoe KD, Pitt HA, Cameron JL. Post-operative bile duct strictures. *Surg Clin North Am* 1990;70:1362.)

that might require drainage (Fig. 61.4). CT and ultrasound are also important in the initial evaluation of the patient presenting with a bile duct stricture months to years after initial operation. Both studies can confirm biliary obstruction by demonstrating a dilated biliary tree. CT is especially useful in identifying the level of obstruction of the extrahepatic bile duct.

In patients suspected of having early postoperative bile duct injury, a radionuclide biliary scan can confirm bile leakage. In patients with postoperative external bile fistula, injection of water-soluble contrast media through the drainage tract (sinography) can often define the site of leakage and the anatomy of the biliary tree.

- 3 The “gold standard” for evaluation of patients with bile duct strictures is cholangiography. Percutaneous transhepatic cholangiography (PTC) is usually more valuable than endoscopic retrograde cholangiography (ERC) in patients with major bile duct injuries following laparoscopic cholecystectomy. PTC is more useful in that it defines the anatomy of the proximal biliary tree that is to be used in the surgical reconstruction (Fig. 61.5). Furthermore, PTC can be followed by placement of percutaneous transhepatic catheters, which can be useful in decompressing the biliary system either to treat or prevent cholangitis and to control an ongoing bile leak. These catheters can also be of assistance in surgical reconstruction and provide access to the biliary tree for nonoperative dilation. ERC is less useful than PTC in major bile duct transections during laparoscopic cholecystectomy because the discontinuity of the extrahepatic bile duct usually prevents adequate filling of the proximal biliary tree (Fig. 61.6). Often, ERC can demonstrate a normal-sized distal bile duct up to the site of the stricture without visualization of the proximal biliary system (Fig. 61.7). This finding is frequently the case in patients with injury during laparoscopic cholecystectomy,

when the distal bile duct is often clipped and divided. The development of magnetic resonance cholangiopancreatography has provided a noninvasive technique that provides excellent delineation of the biliary anatomy. The quality of these images has led some surgeons to advocate this technique as the initial step in the evaluation of patients with suspected bile duct injuries and may eliminate the need for a diagnostic ERC in many patients.

Preoperative Management

The preoperative management of a patient with a postoperative bile duct stricture depends primarily on the timing of the presentation. Patients presenting in the early postoperative period can be septic with either cholangitis or intra-abdominal bile collections. Sepsis must be controlled first with broad-spectrum parenteral antibiotics, percutaneous biliary drainage, and percutaneous or operative drainage of biliary leaks. Once sepsis is controlled, there is no hurry in proceeding with surgical reconstruction of the bile duct stricture. The combination of proximal biliary decompression and external drainage allows most biliary fistulas to be controlled or even to close. The patient can then be discharged home to allow several weeks to elapse for resolution of the inflammation in the periportal region and recovery of overall health.

- 4 The management of a suspected bile duct injury after laparoscopic cholecystectomy presenting with a bile leak deserves special mention. Often, when bile leakage is suspected, the surgeon believes that urgent surgical exploration is necessary. Unfortunately, at laparotomy, the marked inflammation associated with bile spillage and the small decompressed biliary tree that appears retracted high into the porta hepatis make recognition of the injury and repair virtually impossible.

FIGURE 61.5. A: Percutaneous transhepatic cholangiogram demonstrating bile duct stricture at hepatic duct bifurcation with proximal duct dilatation. B: Percutaneous transhepatic cholangiogram demonstrating stricture (arrow) at a hepaticojejunostomy anastomosis. BD, bile duct; int, intestine.

FIGURE 61.6. A: Endoscopic retrograde cholangiogram showing a relatively normal biliary tree in a patient with a postoperative bile collection (see Fig. 61.5). B: Percutaneous transhepatic cholangiogram of same patient, showing entire right hepatic posterior lobe segment obstructed as the result of ligation of the segmental duct. The patient had an unrecognized anatomic variant similar to that shown in Figure 61.2.

In such cases, every attempt should be made to define the biliary anatomy by preoperative cholangiography and to control the bile leak with percutaneous biliary drainage. In many cases, early operative intervention is not required because the bile collections or ascites can either be drained percutaneously or simply is absorbed from the peritoneal cavity. Delayed reconstruction, aided by percutaneous biliary catheters, then allows optimal surgical results.¹⁰

In patients who present with a biliary stricture remote from the initial operation, symptoms of cholangitis can necessitate urgent cholangiography and biliary decompression. Biliary drainage is best accomplished by the transhepatic method, although successful endoscopic stent placement can also be accomplished. Parenteral antibiotics and biliary drainage should be continued until sepsis is controlled. In patients who present with jaundice but without cholangitis, cholangiography should be performed to define the anatomy. Preoperative biliary decompression in patients without cholangitis has not been demonstrated to improve outcome.

Surgical Management

The goal of operative management of bile duct stricture is the establishment of bile flow into the proximal gastrointestinal tract in a manner that prevents cholangitis, sludge or stone formation, restructure, and biliary cirrhosis. This goal is best accomplished with a tension-free anastomosis between healthy tissues. A number of surgical alternatives exist for primary repair of bile duct strictures, including end-to-end repair, Roux-en-Y hepaticojejunostomy or choledochojejunostomy, choledochoduodenostomy, and mucosal grafting. The choice of repair depends on a number of factors, including the extent and location of the strictures, the experience of the surgeon, and the timing of the repair.

Immediate Repair of Intraoperative Bile Duct Injury.

In many cases, initial proper management of bile duct injury recognized at the time of cholecystectomy can avoid the development of a bile duct stricture. Unfortunately, recognition of a bile duct injury is uncommon during either open or laparoscopic cholecystectomy. If bile leakage is observed or atypical anatomy is encountered during laparoscopic cholecystectomy, early conversion to an open technique and prompt cholangiography are imperative. If a segmental or accessory duct less than 3 mm has been injured and cholangiography demonstrates segmental or subsegmental drainage of the injured ductal system, simple ligation of the injured duct is adequate. If

FIGURE 61.7. Endoscopic retrograde pancreaticocholangiogram showing filling of a normal pancreatic duct (PD). The common bile duct (CBD), however, does not fill beyond the large clip that appears to be placed across the duct. (Reproduced with permission from Lillemo KD, Pitt HA, Cameron JL. Postoperative bile duct strictures. *Surg Clin North Am* 1990;70:1363.)

the injured duct is 4 mm or larger, however, it is likely to drain multiple hepatic segments or the entire right or left lobe and thus requires operative repair.

If the injury involves the common hepatic duct or the common bile duct, repair should also be carried out at the time of injury. The aims of any repair should be to maintain ductal length and not to sacrifice tissue as well as to effect a repair that will not result in postoperative bile leakage. To accomplish these goals, all repairs at the time of initial operation should involve some sort of external drainage. If the injured segment of the bile duct is short (<1 cm) and the two ends can be opposed without tension, an end-to-end anastomosis can be performed with placement of a T-tube through a separate choledochotomy

either above or below the anastomosis (Fig. 61.8A). Generous mobilization of the duodenum out of the retroperitoneum (Kocher maneuver) can be useful to help approximate the injured ends of the bile duct. An end-to-end repair, however, should be avoided if the ductal injury is near the hepatic duct bifurcation.

For proximal injuries or if the injured segment of the bile duct is greater than 1 cm in length, an end-to-end bile duct anastomosis should be avoided because of the excessive tension that usually exists in these situations. In these circumstances, the distal bile duct should be oversewn, and the proximal bile duct should be débrided of injured tissue and anastomosed in an end-to-side fashion to a Roux-en-Y jejunal limb. The use of

FIGURE 61.8. All biliary anastomoses performed for the reconstruction of acute bile duct injury should have external drainage. **A:** If the injured segment of bile duct is short (<1 cm) and the two ends can be opposed without tension, an end-to-end anastomosis can be performed with placement of a T-tube through a separate choledochotomy either above or below the anastomosis. The T-tube should not be brought out directly through the anastomosis. **B:** With more proximal injuries or if the segment of injured bile duct is greater than 1 cm, an end-to-end bile duct anastomosis should be avoided and a Roux-en-Y hepaticojejunostomy should be constructed. A transanastomotic stent can be placed retrograde through the transected duct and exited to the hepatic parenchyma to allow postoperative external drainage. (Adapted from Cameron JL. Resection of benign bile duct stricture with reconstruction utilizing Silastic transhepatic biliary stents and hepaticojejunostomy. In: *Atlas of Surgery*, vol 1. Ontario: BC Decker; 1990;47.)

a Roux-en-Y jejunal limb is preferable to anastomosis to the duodenum because, in the latter case, an anastomotic leak results in a duodenal fistula. A transanastomotic Silastic stent can be placed retrograde through the transected duct and exiting the hepatic parenchyma (Fig. 61.8B) to allow for postoperative external drainage.

Unfortunately, most bile duct injuries during laparoscopic cholecystectomy occur in the hands of surgeons who are not experienced in performing complex biliary reconstruction. In such settings, the surgeon should consider *not* repairing the injury and not risk further worsening the situation. The biliary tree should be drained via a retrograde catheter to facilitate cholangiography, but the bile duct should not be ligated. The subhepatic space should be well drained to control the biliary leak. Prompt transfer to a tertiary hepatobiliary center should then be made.

The long-term results of immediate repair of common bile duct injuries are uncertain. Most injuries occur away from major centers, and therefore even the successes are unlikely to be reported in the literature. In a Swedish report, early primary repair with end-to-end anastomosis resulted in good outcomes in only 22% of patients. Anastomotic leak requiring reoperation occurred in 32% of patients, and late stricture occurred in another 37% of patients. In patients undergoing immediate repair with a biliary-enteric anastomosis, good results were seen in 54% of patients, with strictures occurring in only 12% of patients. Similar poor late results were observed in another series in which 29 of 36 patients with primary end-to-end repair had postoperative strictures within 4 years.

Elective Repair of Bile Duct Injuries and Established Strictures. Several principles are associated with successful repair of a biliary injury or stricture: exposure of healthy proximal bile ducts that provide drainage of the entire liver; preparation of a suitable segment of intestine that can be brought to the area of the stricture without tension, most frequently a Roux-en-Y jejunal limb; and creation of a direct biliary-enteric mucosal-to-mucosal anastomosis. A number of alternatives for elective repair of bile duct strictures exist. The choice of procedure is dictated by the location of the stricture, the history of previous unsuccessful attempts at repair, and the surgeon's personal preference. Simple excision of a bile duct stricture and end-to-end bile duct anastomosis or repair of the damaged duct can rarely be accomplished because of the invariable loss of

duct length as a result of fibrosis associated with the injury. Similarly, anastomosis of the proximal bile duct to the duodenum as a choledochoduodenostomy is not suitable for most postcholecystectomy strictures because an adequate length of bile duct for creating a tension-free anastomosis to the duodenum usually cannot be obtained. Thus, in almost all cases, hepaticojejunostomy constructed to a Roux-en-Y limb of jejunum is the preferred procedure.

Many surgeons believe that a transanastomotic stent is helpful in almost all cases. In the early postoperative period, a stent is used to decompress the biliary tree and provide access for cholangiography. If the injury involves the common bile duct or the common hepatic duct at least 2 cm distal to the hepatic duct bifurcation, and adequate proximal bile duct mucosa can be defined, the use of long-term biliary stents is not necessary. In these situations, the preoperatively placed percutaneous transhepatic catheter or operatively placed T-tube is used to decompress the biliary-enteric anastomosis for 4 to 6 weeks after surgery. When adequate proximal bile duct is not available for a good mucosa-to-mucosa anastomosis, long-term stenting of the biliary-enteric anastomosis with a Silastic transhepatic stent is recommended. For strictures involving the hepatic duct bifurcation, both the right and left main hepatic ducts should be individually stented.

An operative technique for biliary reconstruction with transhepatic stents using the preoperatively placed percutaneous transhepatic catheters begins with dissection of the porta hepatis, which usually involves separating adhesions of the duodenum and hepatic flexure of the colon to the Glisson capsule and gallbladder fossa.¹¹ Identification of the proximal biliary segment can be difficult and can be aided by the presence of the transhepatic biliary catheter. This is particularly true for bile duct transections that will retract high into the porta. If a primary duct stricture exists, the bile duct is then divided at the lowest extent of the stricture and dissected proximally. A segment of the strictured duct should be resected and submitted for pathologic examination. The distal duct is then oversewn, and the bile duct proximal to the stricture is carefully dissected circumferentially in a cephalad direction for a distance not to exceed 5 mm. Excessive dissection should be avoided to prevent vascular compromise of this segment of duct, which will be used for the anastomosis. After mobilization and division of the bile duct, the biliary catheters protrude through the proximal end (Fig. 61.9A). A radiologic guide wire is then placed

FIGURE 61.9. Technique of biliary reconstruction. **A:** A Silastic stent is sutured to the preoperatively placed transhepatic catheter, which protrudes through the transected hepatic duct and through the catheter tract in the hepatic parenchyma. **B:** A Roux-en-Y jejunal loop is then anastomosed to the hepatic duct and (C) the Silastic stent is placed through the anastomosis. (*continued*)

FIGURE 61.9. (Continued) D: A completed Roux-en-Y hepaticojejunostomy with a transanastomotic stent. (Adapted from Cameron JL. Resection of benign bile duct stricture with reconstruction utilizing silastic transhepatic biliary stents and hepaticojejunostomy. In: *Atlas of Surgery*, vol 1. Ontario: BC Decker; 1990:45, 55, 57.)

through these catheters. The preoperatively placed catheter can then be exchanged over the wire for a properly sized Silastic stent. These stents are 70 cm long and range from 12 French to 22 French. Multiple side holes are present along 40% of the length of the stent. These side holes are left to reside within the intrahepatic biliary tree and the portion of the Roux-en-Y jejunal limb used for the biliary anastomosis. The end of the stent without the side holes exits through the hepatic parenchyma and is brought out through a stab wound in the upper anterior abdomen. After stent placement, a Roux-en-Y jejunal limb is prepared, and the anastomosis is then performed as an end-to-side hepaticojejunostomy (Fig. 61.9B–D).

An alternative technique has been described for management of bile duct strictures involving the bifurcation and one or both of the hepatic ducts in which a side-to-side anastomosis of the left hepatic duct to the Roux-en-Y limb is constructed. A long opening along the anterior surface of the left hepatic duct is anastomosed to the side of the Roux-en-Y limb. Because it is possible to dissect the anterior surface of the left hepatic duct high up into the hepatic parenchyma, this procedure permits anastomosis to normal mucosa, even though there can be fibrosis and stricture at the bifurcation of the ducts and in the distal portion of the hepatic duct. This technique can avoid the need for postoperative stenting.

Surgical Outcome

Morbidity and Mortality. Repairs of bile duct strictures are performed primarily in major medical centers by experienced surgeons, yet these operations are still associated with significant morbidity and mortality. In 1982, a review of 38 series published since 1900 that included more than 7,643 procedures performed on 5,586 patients reported an overall operative mortality rate of 8.3%.¹² More recently the incidence of operative mortality has decreased markedly with improved technology and a multidisciplinary approach as well as improved surgical experience. A recent series of 200 consecutive patients managed at the Johns Hopkins Hospital reported three deaths in patients who did not undergo an attempt at repair who were referred with sepsis secondary to an uncontrolled biliary leak, for a

mortality rate of 1.5%. Definitive surgical reconstruction was performed in 175 patients with a perioperative mortality of only 1.7%.¹³ In this series the timing of repair, the mode of presentation, previous attempts of repair, and the level of injury did not influence outcome. Chronic liver disease can be an important factor for operative mortality and morbidity with advanced biliary cirrhosis and portal hypertension leading to mortality rates approaching 30%. Fortunately in the modern era, such advanced disease is uncommon. In most series postoperative morbidity rates are in the range of 20% to 40%. In the recent Hopkins series, complications occurred in 41% of patients. Most of the complications were minor and could be managed with either interventional radiology techniques or conservative management. No patient required reoperation for postoperative complications. The median length of stay in this series was 8 days.

Long-term Results. Historically, excellent long-term results were achieved in 70% to 90% of patients who underwent repair of bile duct strictures (Table 61.2). The definition of satisfactory results in most series requires that patients have no symptoms, jaundice, or cholangitis. Length of follow-up is important in analyzing final results because recurrent strictures can occur up to 20 years after the initial procedure (Fig. 61.10).^{8,9} Approximately two thirds of strictures are evident within 2 years, and 90% are seen within 7 years. The percentage of patients with good results is inversely related to the number of previous repairs. Other factors that favor a good outcome include young age at the time of stricture repair, use of a Roux-en-Y biliary-enteric anastomosis, absence of infection and hepatic fibrosis, and use of transhepatic stents.

As illustrated earlier, in the era before laparoscopic cholecystectomy, excellent long-term results were obtainable in tertiary care centers specializing in the management of these problems. Questions had arisen as to whether the excellent results of bile duct strictures after open cholecystectomy could be directly transferred to patients sustaining laparoscopic bile duct injuries. Some researchers had suggested that the mechanism of bile duct injury during laparoscopic cholecystectomy, the complex nature of many of these injuries, and the frequent association of significant inflammation and fibrosis secondary

to sustained, unrecognized bile leakage might result in poor long-term results. Furthermore, the high percentage of these patients who have undergone unsuccessful operations, often performed by the primary laparoscopic surgeon, might also lead to a poor long-term outcome. Evidence for the latter hypothesis was provided by a review of the records of 85 patients who underwent a total of 112 biliary repairs.¹⁴ Four factors determined the success or failure of treatment in this series. These factors included performance of preoperative cholangiography, the choice of surgical repair, details of the operative repair, and experience of the surgeon performing the repair. The importance of preoperative delineation of anatomy was clear, in that 96% of procedures in which cholangiograms were not obtained before repair were unsuccessful, and 69% of repairs were not successful when the cholangiographic data were incomplete. When cholangiographic data were complete, the initial repair was successful in 84% of patients. The type of repair was also of significance in influencing outcome. A primary end-to-end ductal repair over a T-tube was unsuccessful in all patients in whom a complete transection of the bile duct had taken place, whereas 63% of Roux-en-Y hepaticojejunostomies were successful. Attempts at repair by the primary surgeon were successful only in 17% of cases, and in no case was a secondary repair by the primary surgeon successful. In those cases in which the first repair was performed by a tertiary care biliary surgeon, a 94% success rate was obtained.

The outcome of management of 142 patients with major bile duct injuries treated during the 1990s has been reported.¹⁵ Laparoscopic cholecystectomy was the initial operation in 75% of these patients, and 41% had undergone a previous attempt or attempts at surgical repair before referral. In this

series with a median follow-up of 58 months (range, 11 to 119 months), a successful outcome was obtained in 91% of patients. In this series the level of injury, clinical presentation, history of prior repair, and length of biliary stenting did not influence outcome. Comparable results have been reported from other high-volume hepatobiliary centers.^{16,17} These results suggest that surgical reconstruction of major bile duct injuries after laparoscopic cholecystectomy can still result in excellent long-term results.

Despite the overall success of biliary reconstruction, there is a small subset of patients with major bile duct injuries in whom standard repair techniques appear to be inadequate. Factors such as delay in diagnosis, complex injuries above the hepatic confluence, associated vascular injuries, and liver atrophy can all negatively affect the outcomes of standard reconstruction. In this select population excellent results have been observed with major hepatectomy.¹⁸ Finally, in rare cases with failure of all standard surgical techniques of reconstruction with resultant end-stage liver disease, liver transplantation may offer the opportunity for survival.¹⁹

Although large series from tertiary referral centers have reported excellent long-term results, the overall impact of bile duct injuries on society is significant in terms of health care costs, disability, and even mortality. In an analysis of patients undergoing laparoscopic cholecystectomy from the U.S. Medicare database, Flum et al. demonstrated that the adjusted hazard ratio for death during the follow-up period was significantly higher (2.79, 95% confidence level 2.71–2.88) for patients with a bile duct injury than in those patients without a bile duct injury.²⁰ The hazard increased with advancing age and comorbidities and decreased with the experience of the

FIGURE 61.10. The cumulative percentage of recurrent strictures with respect to the time from the initial repair until the next repair. (Adapted from Pitt HA, Miyamoto T, Parapatis SK, et al. Factors influencing outcome in patients with postoperative biliary strictures. *Am J Surg* 1982;144:14.)

repairing surgeon. The adjusted hazard of death during follow-up was 11% greater if the repairing surgeon was the same as the injuring surgeon. These data certainly further support the referral of most patients with bile duct injuries to centers with greater experience in the management of the injuries.

Finally, although the overall success of the surgical management of laparoscopic bile duct injuries associated with laparoscopic cholecystectomy is excellent, there is an impression that patients may have an impaired quality of life even after successful repair of their bile duct injury. Quality-of-life assessments after laparoscopic cholecystectomy bile duct injury have been addressed in several recent reports.^{21,22} These results have generally reported either comparable or mildly diminished quality of life compared with matched controls. Interestingly, in one study, patients who reported pursuing a law suit following their injury had significantly worse quality-of-life scores in all domains when compared to those who did not entertain legal action.²¹

Nonoperative Management

Operative management of bile duct strictures is technically difficult and continues to be associated with significant postoperative morbidity and mortality. Moreover, in all series, recurrent strictures develop in a proportion of patients. These factors, in addition to technical advances in the fields of therapeutic radiology and endoscopy, have led to the development of nonoperative techniques for management of bile duct strictures. The optimal method for management using these techniques is dependent on the presence and anatomy of biliary-enteric continuity.

Percutaneous Balloon Dilation. The management of benign bile duct strictures using the percutaneous transhepatic route is indicated primarily in patients with a failed prior biliary enteric anastomosis to a jejunal limb. The procedure in many cases can be performed with a combination of local anesthesia and intravenous sedation. In this technique, access to the proximal biliary tree is gained and the stricture is traversed with a guide wire under fluoroscopic guidance. At this point, the stricture is dilated using angioplasty-type balloon catheters, chosen on the basis of the location of the stricture and the diameter of the normal duct (Fig. 61.11). After the procedure, a transhepatic stent is left in place across the stricture to allow access to the biliary tree for follow-up cholangiography, repeat dilation, and maintenance of a lumen during the healing process. In most series, numerous dilations are required.

The results from a number of series have been encouraging (Table 61.3). In a multicenter review of bile duct strictures treated in the open cholecystectomy era, 3-year follow-up showed a 67% patency rate for anastomotic and a 76% patency rate for iatrogenic primary bile duct strictures, yielding an overall 70% success rate.²³ A report of 51 patients with bile duct strictures after laparoscopic cholecystectomy managed with percutaneous dilation showed a success rate of 58% with a mean follow-up of 76 months.²⁴

Complications of balloon dilation are frequent. Cholangitis, hemobilia, and bile leaks can occur in up to 20% of patients. Bleeding, usually from the hepatic parenchyma, has been reported, with transfusions often necessary. Sepsis due to cholangitis can occur despite antibiotic prophylaxis. Sepsis and significant bleeding seldom occur in patients dilated by a T-tube tract, suggesting that much of the morbidity is the result of traversing the hepatic parenchyma by the large percutaneously placed catheters.

Endoscopic Balloon Dilation

Endoscopic balloon dilation is technically possible only in patients with primary bile duct strictures or with strictures at

a prior primary end-to-end repair or choledochoduodenal anastomosis. This technique begins with ERC and endoscopic sphincterotomy. The stricture is traversed retrograde with an atraumatic guide wire, and sequential balloon dilation is used. Reevaluation with cholangiography is performed every 3 to 6 months. Redilation is performed as necessary. In most cases, an endoprosthesis is left in place after dilation for at least 12 months.

The reported experience with endoscopic dilation of benign bile duct strictures is shown in Table 61.4. The largest experience comes from the group in The Netherlands who recently reported their experience in 110 patients.²⁵ The mean number of stents placed was two, the mean duration of stenting was 11 months, and stent-related complications occurred in 33% of patients with one death. Twenty percent of patients were eventually referred for surgery. The overall reported success rate was 74% with a mean follow-up of 7.6 years. A similar experience was reported in the United States.²⁶ In this series, 18 of 25 strictures were postoperative. Strictures were located at the cystic duct junction in 17 patients and in the distal bile duct in the remaining eight patients. Of 25 patients, 22 (88%) had significant clinical benefit from the therapy. Only two complications occurred in this series—one case each of pancreatitis and cholangitis.

Comparative Data

Comparison of results of nonoperative dilation with those of surgery have been difficult. Few centers have significant experience with both operative and nonoperative management. Furthermore, the definition of a successful procedure, the reporting of complications, and the length of follow-up have not been consistent in the literature. There are no prospective randomized studies to compare these techniques; however, two retrospective comparative studies exist. In the first study, a retrospective review of the results at the Johns Hopkins Hospital between 1979 and 1987 compared percutaneous balloon dilation and surgery in 43 patients with benign postoperative bile duct strictures.²⁷ Twenty-five patients underwent surgical repair with Roux-en-Y hepaticojejunostomy with postoperative transhepatic stenting for a mean of 13 ± 1.3 months. Twenty patients had percutaneous balloon dilation, a mean of 3.9 times, and were stented transhepatically for a mean of 13.3 ± 2 months. Three patients were managed with both surgery and balloon dilation. The two groups were similar with respect to multiple parameters that might have influenced outcome, including age, sex, associated medical problems, and presentation with either obstructive jaundice or biliary fistulas. No patients died after any of the procedures. Procedure-related morbidity occurred in 20% of surgical patients and in 35% of the patients undergoing balloon dilation. For both groups, a successful outcome was defined as no evidence of cholangitis or jaundice requiring another procedure more than 12 months from the onset of treatment. A failed treatment was defined as the need for crossover to the other treatment modality, either operation or dilation, or late death from liver failure, biliary sepsis, or portal hypertension. A successful repair was achieved in 89% of the surgical patients and in only 52% of the balloon dilation patients (Fig. 61.12). The overall late mortality rate in this series was 10%. One late death occurred in the surgical group, whereas three late deaths followed balloon dilation (4% vs. 15%, respectively). No deaths, however, were attributed to liver failure, biliary sepsis, or portal hypertension associated with the bile duct stricture.

To define further the relative benefits of the two procedures, total hospital stay and total procedural costs were determined. As expected, initial hospitalization was longer for surgery than for balloon dilation. When rehospitalization for further dilation, complications, or recurrences was considered, total hospital stay did not differ significantly between the two

7 groups. Cost data paralleled hospitalization data and did not differ significantly between the groups. Thus, the authors concluded that until properly designed, randomized, prospective, controlled trials can be performed, surgical repair for benign postoperative strictures appears to be associated with fewer problems and a greater success rate.

In the second comparative study, the group from The Netherlands compared endoscopic versus surgical treatment of benign bile duct strictures.²⁸ Thirty-five patients were treated surgically, and 66 were treated by endoscopic stenting. Patient characteristics, initial injury, previous repairs, and the level of obstruction were comparable in both groups. Surgical therapy consisted of Roux-en-Y hepaticojejunostomy, and endoscopic therapy consisted of placement of an endoprosthesis with trimonthly elective exchange for 1 year. Successful stent placement was accomplished in 94% of patients managed endoscopically. Six of the 66 endoscopic patients, however, underwent surgical reconstruction either for failed stent placement or for other reasons. Early complications occurred more frequently in the surgically treated group (26% vs. 8%; $p < 0.03$). However, the only procedure-related death occurred in a patient in whom severe pancreatitis developed after endoscopic stent placement. Late complications, which included primarily episodes of cholangitis, occurred only in the endoscopic group (27%). The overall complication rates, therefore, were similar at 26% for surgical patients and 35% for endoscopic patients. The mean follow-up and definition of success were similar to those in the aforementioned study. After surgery, excellent results were observed in 83% of patients, with a recurrent stricture developing in six patients at a mean of 40 months after the initial operation. After endoscopic stenting, excellent results were observed in 72% of patients, with resticture developing in 18% of patients at a mean of 3 months after stent removal. The

investigators concluded that endoscopic stenting should be considered for the initial attempt at definitive management in suitable patients in the hope of avoiding reoperation.

PRIMARY SCLEROSING CHOLANGITIS

8 Primary sclerosing cholangitis is an idiopathic disease characterized by intrahepatic and extrahepatic inflammatory strictures of the bile ducts that cannot be attributed to other specific causes. The cause of primary sclerosing cholangitis is unknown. Many experts consider primary sclerosing cholangitis to be an autoimmune reaction because it is associated with other autoimmune diseases, such as ulcerative colitis, retroperitoneal fibrosis, and Riedel thyroiditis (Table 61.5). It is likely that a number of causes, including viral or bacterial infections, toxic drug reactions, and congenital anomalies, can all result in the same end-stage injury that is recognized as primary sclerosing cholangitis.

The usual clinical presentation of patients with primary sclerosing cholangitis involves intermittent jaundice, which begins insidiously in the fourth or fifth decade of life. Right upper quadrant pain, pruritus, fever, weight loss, and fatigue can also occur. The disease is characterized by cyclic remissions and exacerbations. Despite the nomenclature, acute

FIGURE 61.12. Actuarial success rates over 72 months for surgery (89%) and balloon dilation (52%). The difference is statistically significant ($p < 0.01$). (Adapted from Pitt HA, Kaufman SL, Coleman J, et al. Benign postoperative biliary strictures: operate or dilate? *Ann Surg* 1989;210:417.)

TABLE 61.5**DISEASES ASSOCIATED WITH PRIMARY SCLEROSING CHOLANGITIS**

■ DISEASE	■ FREQUENCY (%)
Ulcerative colitis	40–60
Pancreatitis	12–25
Diabetes mellitus	5–10
Retroperitoneal fibrosis	Rare
Riedel thyroiditis	Rare
Crohn disease	Rare
Histiocytosis X	Rare
Sicca complex	Rare
Rheumatoid arthritis	Rare
Hypertrophic osteoarthropathy	Rare
Sarcoidosis	Rare
Angioimmunoblastic lymphadenopathy	Rare
Acquired immunodeficiency syndrome	Rare

FIGURE 61.13. **A:** Cholangiogram of a patient with primary sclerosing cholangitis. Multiple irregular strictures and dilatation (beading) of intrahepatic bile ducts can be seen. **B:** Endoscopic retrograde cholangiogram showing extensive involvement of extrahepatic bile duct (BD) with primary sclerosing cholangitis. (B reproduced with permission from Lillemoe KD, Pitt HA, Cameron JL. Primary sclerosing cholangitis. *Surg Clin North Am* 1990;70:1390.)

cholangitis is uncommon without previous biliary manipulation or surgery. The diagnosis is suggested by clinical presentation associated with cholestatic liver function test abnormalities. The levels of bilirubin often fluctuate with respect to the remissions and exacerbations of the disease and the extent of hepatic injury. Alkaline phosphatase is usually elevated out of proportion to the serum bilirubin, and is a more persistent finding. The diagnosis, however, usually is confirmed by cholangiography, which reveals multiple dilations and strictures (beading) of the intrahepatic and extrahepatic bile ducts (Fig. 61.13). Magnetic resonance cholangiopancreatography (MRCP) has become the preferred procedure as it is noninvasive. ERC, however, remains an important tool for both diagnostic and therapeutic procedures. An important distinction must be made as cholangiocarcinoma must be considered in the differential diagnosis of a dominant stricture. Furthermore, cholangiocarcinoma may develop after presentation in up to 30% of patients with primary sclerosing cholangitis. Therefore, endoscopic brushings and biopsies are frequently required. The disease should be followed closely by cholangiography and liver biopsy to provide appropriate management before the development of biliary cirrhosis.

No known specific medical therapy is effective for primary sclerosing cholangitis. The most encouraging results, from a prospective, randomized, placebo-controlled trial, suggest that ursodeoxycholic acid significantly improves serum liver function tests and liver histologic appearance. Unfortunately, there were no significant differences in clinical outcome between the two groups at up to 6 years of follow-up.²⁹ Nonoperative dilation therapy by the endoscopic route has been used for dominant strictures with favorable results.³⁰

An aggressive surgical approach is advocated for selected symptomatic patients with primary sclerosing cholangitis because of the lack of effective medical therapy. One surgical

approach, in patients with a dominant stricture at the hepatic duct bifurcation, uses resection of the bifurcation and long-term transhepatic stenting with Silastic stents. This mode of therapy was recently reported in 77 patients with resection of the hepatic duct bifurcation, with hepatic lobectomy performed in another four patients.³¹ The perioperative complication rate was 39% and 30-day mortality was 3.9%. Bilirubin improved and 57% of patients had no primary sclerosing cholangitis-related readmissions. At median follow-up of 10.5 years, the 5- and 10-year survival rates were 76.4% and 52.7%, respectively. Cholangiocarcinoma did not develop in any patients and only seven required liver transplant. Over the same period, liver transplant was performed in 49 patients with cirrhosis with a 10-year survival of 57%.

The role of biliary surgery in primary sclerosing cholangitis, however, has decreased considerably with the growing success of liver transplantation. Primary sclerosing cholangitis has become one of the most common indications for liver transplantation in the United States, with 5-year actuarial survival and graft survival rates of 85% and 72%, respectively.³² Liver transplantation should be considered before the disease is too advanced. The development of a poor quality of life as a result of disabling fatigue, intractable pruritus, severe muscle wasting, and chronic or recurrent bacterial cholangitis or persistent elevations in serum bilirubin are primary indications for referral for liver transplantation.

Preoperative recognition of cholangiocarcinoma is extremely important in this population in that the development of this complication significantly worsens the result after liver transplantation. The presence of known malignancy results in patients being refused transplantation. The microscopic identification of intrahepatic cholangiocarcinoma in the absence of lymph node involvement, often demonstrated in the explanted liver specimen, however, does not usually portend a poor prognosis.

FIGURE 61.14. Actuarial survival rates among 31 noncirrhotic patients with primary sclerosing cholangitis who underwent resection of the hepatic bifurcation and long-term transhepatic stenting. (Reproduced with permission from Lillemoe KD, Pitt HA, Cameron JL. Primary sclerosing cholangitis. *Surg Clin North Am* 1990;70:1397.)

Patients with primary sclerosing cholangitis have a significantly higher rate of development of nonanastomotic biliary strictures after liver transplantation, with histologic features on posttransplantation biopsy consistent with recurrence of the disease. Other causes of stricture, such as hepatic artery thrombosis, preservation-related ischemia, cytomegalovirus infection, and chronic ductopenic rejection, can cause similar lesions. Recurrent primary sclerosing cholangitis usually does not have an aggressive course.

Resection of the hepatic duct bifurcation and long-term transanastomotic stenting in selected patients can preclude or delay the need for hepatic transplantation. Moreover, this operation does not eliminate or influence the results of hepatic transplantation. Resection of the hepatic bifurcation and long-term transhepatic stenting can be recommended for selected patients with primary sclerosing cholangitis with severe strictures at or distal to the hepatic duct bifurcation but without established biliary cirrhosis. In patients with biliary cirrhosis, hepatic transplantation is recommended.

BILE DUCT STRICTURES SECONDARY TO CHRONIC PANCREATITIS

Chronic pancreatitis is an uncommon cause of benign bile duct strictures, resulting in less than 10% of such cases. Transient partial obstruction of the distal common bile duct caused by inflammation and edema frequently occurs in patients with acute pancreatitis. With chronic pancreatitis, however, the clinical problem is distal bile duct obstruction caused by inflammation and parenchymal fibrosis of the gland. These strictures classically involve the entire intrapancreatic segment of the common bile duct and are associated with dilatation of the entire proximal biliary tree (Fig. 61.14). In most cases, the cause of the chronic pancreatitis is alcoholism. Often, advanced disease is present in that the incidence of pancreatic calcification, diabetes, and malabsorption is increased at the time of presentation with jaundice compared with patients with chronic pancreatitis without jaundice. Common bile duct strictures have been reported to occur in 3% to 29% of patients with chronic alcoholic pancreatitis. In a review of a number of clinical series, the overall incidence of common bile duct strictures in patients with chronic pancreatitis was 5.7%.³³ The exact incidence of common bile duct strictures is not known, however, because cholangiography is not routinely performed in patients with chronic pancreatitis.

The clinical presentation of patients with common bile duct strictures secondary to chronic pancreatitis is variable. Some patients have no symptoms, with the diagnosis of bile duct strictures suggested only by abnormal liver function test results. The serum alkaline phosphatase appears to be the most sensitive laboratory finding and is elevated in more than 80% of patients. Abdominal pain with or without jaundice is

another common presentation. In some cases, the abdominal pain can be difficult to distinguish from the pain associated with chronic pancreatitis. Failure to recognize and address a bile duct stricture, however, can lead to ultimate failure of operative procedures performed for chronic pain in patients with chronic pancreatitis. Finally, the development of jaundice in patients with chronic pancreatitis must be differentiated from underlying periampullary malignancy.

The definitive evaluation of patients with a bile duct stricture caused by chronic pancreatitis is cholangiography. Either MRCP or endoscopic retrograde cholangiopancreatography (ERCP) is the preferred diagnostic procedure as they both can demonstrate both biliary and pancreatic ductal anatomy, which is essential in optimal surgical management of chronic pancreatitis. ERCP with stenting allows decompression of the obstructed biliary tree if necessary for cholangitis or severe jaundice. A long (usually 2- to 4-cm), smooth, gradual tapering of the common bile duct is most compatible with a benign stricture due to chronic pancreatitis (Fig. 61.15).

The indications for surgical management of common bile duct strictures due to chronic pancreatitis are clear in patients

FIGURE 61.15. Cholangiogram of a patient with a long distal common bile duct stricture (arrow) caused by chronic pancreatitis.

9 with significant pain, jaundice, or cholangitis. Controversy exists, however, concerning the necessity of biliary decompression in patients with an asymptomatic elevation of serum alkaline phosphatase. In general, biliary bypass is indicated because changes from obstructive biliary cirrhosis have been observed in liver biopsy specimens obtained from patients with long-standing, functionally significant biliary obstruction due to chronic pancreatitis.^{34,35}

Choledochoduodenostomy and Roux-en-Y choledochojejunostomy are acceptable methods of biliary bypass in patients with bile duct strictures caused by chronic pancreatitis. Choledochoduodenostomy is preferred by many surgeons because it does not divert bile from the duodenum, is technically easier to perform, and leaves the jejunum intact for any associated procedures required for decompression of an obstructed gastrointestinal tract or pancreatic duct. Finally, in patients in whom periampullary malignancy cannot be completely ruled out by the clinical course or imaging studies, or in patients with significant chronic pain thought secondary to proximal pancreatic duct disease, pancreaticoduodenectomy offers an excellent treatment option. The results of surgical management of distal bile duct strictures due to chronic pancreatitis are usually excellent, with a low rate of perioperative complications and excellent long-term results.

Transduodenal sphincteroplasty is not recommended for the management of common bile duct strictures caused by chronic pancreatitis because the stricture is too long to be managed adequately by this technique. Similarly, endoscopic sphincterotomy has no role in the management of biliary obstruction due to chronic pancreatitis. Limited experience has been reported with balloon dilation of distal bile duct strictures secondary to pancreatitis, with little long-term follow-up.

Over the last decade another variant of chronic pancreatitis has been recognized as a cause of distal bile duct stricture—autoimmune pancreatitis.³⁶ This process is characterized by a lymphoplasmacytic infiltrate and is associated with secretion of large amounts of immunoglobulin (Ig) 4. The condition can mimic pancreatic cancer and is diagnosed by characteristic imaging studies and elevation of serum Ig4 levels. Treatment is with corticosteroids with surgical resection or bypass reserved for unresponsive cases or when a diagnostic dilemma remains.

MISCELLANEOUS CAUSES OF BILE DUCT STRICTURES

Benign strictures of the bile duct can result from the chronic inflammation associated with gallstones in either the gallbladder or common bile duct. This cause of bile duct strictures is uncommon and is a rare complication of gallstone disease. Bile duct strictures caused by cholelithiasis are usually associated with a narrowing at the level of the common hepatic duct caused by a stone impacted in the infundibulum of the gallbladder. The narrowing can be caused by two means. First, simple compression can occur from a large stone lying adjacent to the common hepatic duct. Second, chronic or acute inflammation arising from the gallbladder or cystic duct can extend to the contiguous bile duct, resulting in stricture formation. The biliary obstruction associated with either of these conditions is known as *Mirizzi syndrome*.

The clinical presentation of a bile duct stricture caused by cholelithiasis is often associated with acute cholecystitis and hyperbilirubinemia. In some long-standing cases, these findings exist in the face of chronic gallbladder symptoms. If hyperbilirubinemia is present and urgent cholecystectomy is not indicated, ERCP or PTC can help to delineate the preoperative biliary anatomy. Most cases that are associated with acute cholecystitis, however, are recognized at the time of cholecystectomy and operative cholangiography. When the

duct compression is associated with acute inflammation, the common hepatic duct almost always returns to normal after the offending stone has been removed by cholecystectomy and the inflammatory process has resolved. Care must be taken during the dissection to avoid creation of a defect in the common hepatic duct. Rarely, after the acute episode has resolved, a well-established stricture presents months to years after the acute episode. In such cases, management by Roux-en-Y hepaticojejunostomy is appropriate.

Strictures due to choledocholithiasis are also rare. The presumed mechanism is erosion of the epithelium of the distal duct, creating inflammation with subsequent fibrosis and stricture. Because of the anatomic tapering of the common bile duct, nearly all stones are entrapped in the intrapancreatic portion of the duct and are often difficult to remove by the supraduodenal route.

Excessive intraoperative manipulation at the time of bile duct exploration with forceps, scoops, and catheters can often create additional trauma to an already friable distal duct. After the stone has been removed, the distal bile duct should be gently sized with a soft rubber catheter to be sure that no stricture exists. If a stricture persists after stone removal, it may not be recognized until the time of postoperative T-tube cholangiography. If recognized in the postoperative period, time should be allowed for resolution of inflammation before considering stricture repair. If a distal bile duct stricture does persist, a biliary-enteric anastomosis with either Roux-en-Y choledochojejunostomy or a choledochoduodenostomy is indicated. If the proximal duct is adequately dilated (>2 cm in diameter) to allow a large choledochoduodenal anastomosis, this procedure is usually preferable because of its technical ease and excellent results.

Stenosis of the sphincter of Oddi, or papillitis, is a benign intrinsic obstruction of the outlet of the common bile duct, usually associated with inflammation, fibrosis, or muscular hypertrophy. Sphincter stenosis can result in any of three clinical conditions: (a) common bile duct obstruction due to fibrotic stenosis of the papilla, (b) recurrent pancreatitis, or (c) recurrent right upper quadrant pain without jaundice or pancreatitis. The pathogenesis of the inflammation of sphincter stenosis is unclear. In many cases, it is thought to result from the trauma of the passage of multiple small stones from the common duct through the ampulla. This trauma results in inflammation, scarring, and stricture formation. Many patients with papillary stenosis have no gallstones. Other potential mechanisms include primary sphincter motility disorders and congenital anomalies. The clinical presentation is usually either jaundice or cholangitis. In some cases, an impacted common bile duct stone may be present. The diagnosis can be supported with either PTC or ERC. This condition can be managed by sphincterotomy performed either endoscopically or operatively. If a cholecystectomy was performed previously, endoscopic papillotomy is the initial procedure of choice.

Cholangiohepatitis is an unusual infection of the biliary tree frequently associated with *Clonorchis sinensis* and other parasites. These infections are most commonly seen in natives of Asia. Most patients present with recurrent episodes of cholangitis. Cholangiography can demonstrate multiple strictures of both the intrahepatic and extrahepatic biliary tree, with the bile ducts filled with sludge and stones (Fig. 61.16). Surgical management consists of cholecystectomy and improved biliary drainage with either Roux-en-Y choledochojejunostomy or choledochoduodenostomy. Access to the biliary tree for postoperative management of intrahepatic stones or sludge should be maintained with either transhepatic biliary stents or a choledochojejunocutaneous or subcutaneous fistula. No specific medical management is available for this condition.

Finally, rare causes of benign intrahepatic and extrahepatic bile duct strictures have been reported secondary to intrahepatic arterial infusion of 5-fluorouracil used in the treatment of hepatic metastases of colorectal carcinoma. The clinical picture

FIGURE 61.16. Cholangiogram of a patient with cholangiohepatitis with diffuse bile duct dilatation. The biliary tree is filled with sludge (SI) and stones.

closely resembles primary sclerosing cholangitis but usually can be managed by simple discontinuation of infusion and, in some cases, percutaneous transhepatic drainage. Surgery should be reserved for patients with persistent evidence of biliary obstruction. A similar cholangiographic appearance has been reported in patients with acquired immunodeficiency syndrome. The pathogenesis of this injury is believed to be viral and related to cytomegalovirus infection. No experience in the surgical management of this condition has been reported.

CHAPTER 62 ■ BILIARY NEOPLASMS

SHARON WEBER, BRETT YAMANE, AND YUMAN FONG

KEY POINTS

- 1 Surgery remains the only curative option for biliary malignancies.
- 2 Gallbladder cancer is a rare malignancy with a dismal outlook because of its insidious onset, propensity for local invasion, and rapid disease progression.
- 3 The association of gallstones with carcinoma is probably related to chronic inflammation.
- 4 Patients with choledochal cysts have an increased risk of carcinoma developing anywhere in the biliary tree, but the incidence is highest in the gallbladder.
- 5 The only curative option in patients with gallbladder cancer is complete surgical resection.
- 6 Nonoperative palliative biliary decompression can be accomplished with percutaneous or endoscopic stenting, depending on the level of obstruction.
- 7 To date, no chemotherapeutic regimen has consistently shown activity against cholangiocarcinoma.

Tumors arising in the gallbladder and biliary tree are often asymptomatic until late in the course of the disease. Consequently, these tumors commonly present in an advanced, often unresectable, stage. Surgery remains the only curative option for biliary malignancies. Resection of biliary neoplasms, however, often requires radical resections and complex biliary reconstructions that have only recently become safe in routine practice. Surgery also offers effective palliation for these cancers, including biliary bypasses for jaundiced patients with unresectable tumors. Both the late diagnosis and the complex operative techniques required for potentially curative resection contribute to the challenge of these cases. In addition, there are no proven effective options for adjuvant treatment. This chapter reviews the incidence, diagnosis, and therapy of these malignancies as well as the outcome of treatment.

GALLBLADDER CARCINOMA

- 2 Gallbladder cancer is a rare malignancy with a dismal outlook because of its insidious onset, propensity for local invasion, and rapid disease progression. Overall, most series report a 5-year survival of less than 5%. The extent of surgical resection remains ill defined because of the rarity of this lesion and its poor prognosis.

Incidence

Only 6,000 to 7,000 new cases of gallbladder cancer are diagnosed nationally each year.¹ Attesting to the rarity of this lesion, after routine screening of abdominal ultrasounds in asymptomatic patients in Japan, only 19/194,767 (0.01%) were found to have gallbladder cancer.² This tumor occurs more frequently in women (female-to-male ratio = 3:1), and peak incidence is in the seventh decade.¹ There is an increased risk of gallbladder cancer in Native American populations of the United States and Mexico.³ The increased risk of gallbladder cancer with cholelithiasis is well established; 70% to 90% of all patients with carcinoma also have gallstones. However, less than 0.5% of patients with gallstones are found to have gallbladder cancer.³ After elective cholecystectomy for gallstones, gallbladder cancer is found incidentally in 1% of

- 3 patients.⁴ The association of gallstones with carcinoma is probably related to chronic inflammation. Larger stones (>3 cm) are associated with a 10-fold increased risk of cancer.⁵

The association of gallbladder cancer with gallstone disease has led some investigators to question whether all patients with gallstones should undergo cholecystectomy. The argument against this approach is that the use of cholecystectomy only for symptomatic patients, thus leaving the gallbladder in place in patients with asymptomatic gallstones, has not led to an increase in the prevalence of gallbladder cancer over time. Also, epidemiologic studies have found that the 20-year risk of developing cancer in patients with gallstones is less than 0.5% for the overall population and 1.5% for high-risk groups.³ Thus, routine cholecystectomy for asymptomatic gallstones because of concern for gallbladder cancer does not appear to be warranted.

In the past, the finding of a calcified gallbladder wall, called “porcelain gallbladder” (Fig. 62.1), was associated with a high risk of cancer, in some series ranging from 25% to 60%.⁶ Thus, the recommendation was for all patients with porcelain gallbladder to undergo open cholecystectomy, even if asymptomatic. Recent series evaluating this issue, however, suggest that the risk of gallbladder cancer in patients with porcelain gallbladder has likely been greatly overestimated.^{7,8} In fact, although patients with limited areas of calcification of the wall may have a higher incidence of gallbladder cancer (7%), patients with diffuse calcification of the gallbladder wall, the classic presentation for porcelain gallbladder, do not appear to have an increased risk of gallbladder cancer.^{7,8}

- 4 Patients with choledochal cysts have an increased risk of carcinoma developing anywhere in the biliary tree, but the incidence is highest in the gallbladder. This risk increases with age. Therefore, complete surgical resection is recommended for all patients with choledochal cysts at the time of diagnosis.

Pathology and Staging

More than 80% of gallbladder cancers are adenocarcinomas; there are several histologic subtypes, including papillary, nodular, and tubular. Papillary tumors, which grow predominantly into the gallbladder lumen, have an improved prognosis compared with the other subtypes.⁹ Poor prognostic signs in

FIGURE 62.1. Unresectable gallbladder cancer demonstrating palliative transhepatic percutaneous stent placed to relieve jaundice. Porcelain gallbladder is present (arrows).

gallbladder cancer include grade^{9,10} and vascular invasion.⁹ The most important prognostic sign may be lymph node status,¹¹ although 5-year survivors with nodal involvement have been documented.¹² Less than 5% of cases are squamous cell carcinomas, with the remaining 10% being anaplastic lesions.

Gallbladder cancer spreads via the lymphatic and venous drainage. Because of drainage of the cholecystic veins directly into the adjacent liver, these tumors often involve hepatic parenchyma, most often portions of segments IV and V. Lymphatic spread is first to the cystic duct (Calot) node, then to pericholedochal and hilar nodes, and finally to peripancreatic, duodenal, periportal, celiac, and superior mesenteric artery nodes. Nodal disease in the porta hepatis often causes common bile duct obstruction and resultant jaundice, which is the first clinical symptom in 30% of patients. Jaundice may also be caused by tumors arising in the infundibulum, which may spread directly to the cystic duct and common hepatic duct. Although peritoneal metastases are frequent, distant extraperitoneal metastases are not.

Limited information exists regarding the genetic changes in gallbladder cancer. The most widely reported gene abnormalities associated with gallbladder cancer include p53,¹³ K-ras,^{13,14} and CDKN2 (9p21) mutations.^{14,15} The finding that patients with an anomalous pancreaticobiliary junction have a greater frequency of K-ras mutations has led investigators to believe that reflux of pancreatic enzymes into the biliary tree may contribute to the development of cancer.¹⁴ Because of our limited knowledge of the sequence of molecular changes, there are no known detectors of early disease or of risk assessment. Clearly, this is an area that needs improvement, particularly in endemic areas.

The American Joint Committee on Cancer's (AJCC) seventh edition of its tumor, node, metastasis (TNM) staging system (Table 62.1) reflects prognostic characteristics of tumor depth, regional nodal disease, and distant spread. The gallbladder

differs histologically from the rest of the gastrointestinal tract in that it lacks a muscularis mucosa and submucosa. The gallbladder wall is composed of (a) a single layer of columnar cells, the mucosa, and lamina propria; (b) a fibromuscular layer; (c) a perimuscular, subserosal layer containing lymphatics and neurovascular structures; and (d) a serosal surface, except where the gallbladder is embedded in the liver.¹⁶ Because lymphatics are present in the subserosal layer only, tumors invading less than the full thickness of the muscular layer have minimal risk of nodal spread. Thus, disease invading into, but not through, the muscular layer of the gallbladder is stage IB disease, whereas invasion into the perimuscular connective tissue is stage II. Stage III disease includes tumors that have perforated the serosa or have directly invaded the liver or other surrounding structures, which are clearly more advanced but still potentially resectable. Lymph node metastasis is now classified as stage IIIB. In line with other pancreaticobiliary malignancies, the stage III grouping refers to locally advanced disease and stage IV indicates metastatic disease.

Clinical Findings and Diagnosis

Most patients are found to have gallbladder cancer during workup or treatment of cholelithiasis or choledocholithiasis. In patients with symptoms, abdominal pain consistent with biliary colic or acute cholecystitis is most common. Patients also present with jaundice, weight loss, anorexia, or an increase in abdominal girth secondary to ascites. Physical findings include right upper quadrant tenderness or a palpable mass, hepatomegaly, and ascites. Laboratory investigation, if abnormal, is most often consistent with biliary obstruction. Because of its nonspecific presentation and the lack of reliable screening tests, gallbladder cancer is not diagnosed preoperatively in more than half the cases.

Imaging evaluation often reveals a thickened gallbladder wall or a mass within or replacing the gallbladder on ultrasound examination. Because polyps and carcinoma can have an echogenicity similar to the gallbladder wall, these lesions are often difficult to distinguish. This is even more difficult when inflammation is present from gallstones. At times, ultrasound can visualize invasion of the liver, adjacent adenopathy, and a dilated biliary tree. The ability of ultrasound to differentiate benign from neoplastic disease is enhanced using endoscopic ultrasound, and may be more specific than computed tomography (CT) or magnetic resonance imaging (MRI).^{17,18}

A dynamic contrast-enhanced CT scan may identify a gallbladder mass or invasion into the liver parenchyma or adjacent organs. The classic finding in a patient with gallbladder cancer is asymmetric thickening of the gallbladder wall. The sensitivity and specificity of contrast-enhanced CT in diagnosing neoplastic lesions is close to 90%.⁶ Staging of gallbladder carcinoma using CT, however, is limited by poor sensitivity in identifying nodal spread.¹⁹

In patients who are jaundiced, direct cholangiography may be useful to delineate the extent of biliary involvement as well as to palliate symptoms of biliary obstruction. A mid-bile duct obstruction not caused by gallstones is gallbladder cancer until proved otherwise (Fig. 62.2). More recently, with improvements in MRI technology, magnetic resonance cholangiopancreatography (MRCP) has evolved into a single, noninvasive imaging modality that allows complete assessment of biliary, vascular, hepatic parenchymal, and nodal involvement, as well as involvement of adjacent organs (Fig. 62.3).^{20–22}

Surgery

It is clear that the only curative option in patients with gallbladder cancer is complete surgical resection. It is essential for optimal patient care that patients with gallbladder cancer be

DEFINITION OF TNM

Primary tumor (T)

TX

Primary tumor cannot be assessed

T0

No evidence of primary tumor

Tis

Carcinoma in situ

T1

Tumor invades lamina propria or muscular layer

T1a

Tumor invades lamina propria

T1b

Tumor invades muscular layer

T2

Tumor invades perimuscular connective tissue; no extension beyond serosa or into liver

T3

Tumor perforates the serosa (visceral peritoneum) and/or directly invades the liver and/or one other adjacent organ or structure, such as the stomach, duodenum, colon, pancreas, omentum, or extrahepatic bile ducts

T4

Tumor invades main portal vein or hepatic artery or invades two or more extrahepatic organs or structures

Regional lymph nodes (N)

NX

Regional lymph nodes cannot be assessed

N0

No regional lymph node metastases

N1

Nodes confined to the hepatic hilus (including nodes along the common bile duct, hepatic artery, portal vein, and cystic duct

N2

Metastases to celiac, periduodenal, peripancreatic, and/or superior mesenteric artery lymph nodes

Distant metastasis (M)

M0

No distant metastasis

M1

Distant metastasis

recognized before laparoscopic cholecystectomy is performed, because of the risk of port site seeding and bile spillage, with its potential for subsequent carcinomatosis.²³

Role of Staging Laparoscopy. Because a large percentage of patients with gallbladder cancer are found to have occult, unresectable disease at the time of surgical exploration, several authors have investigated the use of initial staging laparoscopy for this disease.^{24–27} Because gallbladder cancer has such a propensity to spread intra-abdominally, this tumor is ideal for detection of intra-abdominal metastases with laparoscopy. This is demonstrated by the fact that up to 50% of patients are found to have unresectable disease at the time of laparoscopy.^{24,28} Patients who are found to have unresectable disease at laparoscopy can begin other forms of systemic therapy earlier and may undergo the procedure as an outpatient. Particularly because patients with unresectable disease have a median survival of only 6 months, the impact on quality of

life, including decreased length of stay in the hospital, cannot be overemphasized.

Cholecystectomy with or without Partial Hepatectomy.

Gallbladder cancer, if not completely surgically removed, results in rapid local progression and death. In a collected review of 5,836 patients with gallbladder cancer, the overall mean survival was between 2 and 5 months, whereas the 5-year survival was 4%.³ The 5-year survival of patients undergoing resection with curative intent was 17%. Of the 2,115 patients with unresectable disease, only a single survivor was found at 5 years.³ Although surgical resection represents the treatment of choice and the only potentially curative therapy available, resection is possible in only 25% of patients at presentation because of the advanced nature of the disease.³

There is little doubt that the results of treatment, as well as the scope of operation, are related to depth of tumor penetration (Table 62.2). For tumors limited to the muscular layer of

FIGURE 62.2. Endoscopic retrograde cholangiopancreatogram obtained from a patient with gallbladder cancer. Mid-bile duct obstruction (*arrow*) is caused by direct extension of tumor to the cystic and common hepatic duct.

the gallbladder (T1), there is near-universal agreement that simple cholecystectomy is adequate.^{12,29–31} T1 tumors have not yet invaded the subserosal layer, which contains lymphatics, and therefore lymphadenectomy is not required. Attesting to the fact that early gallbladder carcinoma is completely curable, simple cholecystectomy has resulted in 90% to 100% survival

FIGURE 62.3. T₁-weighted magnetic resonance imaging scan of a patient with gallbladder cancer (*small arrows*) with extension into the duodenum and the hepatic flexure of colon (*large arrows*).

when early cancer is an incidental finding after elective cholecystectomy.^{12,32}

Difficulty can arise at the time of surgery in evaluating polypoid lesions of the gallbladder as either benign or early gallbladder cancer. Although it appears that frozen section diagnosis is fairly reliable in distinguishing whether lesions are malignant or benign (95% accurate), the accuracy in correctly assessing depth of invasion is only 70%.³³ Thus, it may be difficult at the time of surgery to determine the extent of resection. Because of this, pursuing a more aggressive resection if the depth of invasion is in doubt is important for adequate tumor clearance.³²

The extent of surgical resection for T2 or greater tumors is controversial, with recommendations ranging from simple cholecystectomy to radical excision, including hepatectomy. For advanced local disease, some groups have advocated radical

resections, including hepatectomy and pancreatectomy. Whereas it is clear that major hepatic resection can be performed safely with a mortality less than 5% (Table 62.3)^{11,12,30–32,34} it has not been universally accepted that more aggressive resections improve survival. To understand the rationale for extensive resections, it is also important to understand the pattern of spread of gallbladder cancer. Direct extension to the adjacent liver parenchyma often occurs first, followed by adjacent organ involvement, including duodenum, colon, and stomach (Fig. 62.2). Lymphatic spread of gallbladder cancer is routine, often involving nodes in the porta hepatis, peripancreatic region, celiac axis, and the aortocaval nodal basins.

Because the gallbladder is not surrounded by serosa where it is attached to the liver in the gallbladder fossa, even T2 tumors (full-thickness invasion of the muscular layer into the perimuscular connective tissue, no extension beyond serosa or into liver) can invade the normal plane of dissection in the gallbladder fossa during simple cholecystectomy. Therefore, T2 tumors cannot be completely removed with cholecystectomy alone, and a radical cholecystectomy, with resection of a 1- to 2-cm rim of normal liver around the gallbladder fossa, is the minimal resection that is required. Many authors, however, have found that segmental resection of segments IVb and V of the liver, which about the gallbladder fossa, results in a more anatomically controlled dissection with less blood loss.³⁵ An additional part of the definitive surgical treatment is regional lymphadenectomy, because about half the patients with T2 tumors are found to have nodal spread after resection.¹¹ Dissection of lymph nodes should include all tissue from the bifurcation of the hepatic ducts to the distal common bile duct. Proponents of this approach advocate liver resection on the basis that it is the only way to obtain an adequate margin on the hepatic side of the gallbladder and resection of the regional nodes allows the best chance for complete tumor clearance. For all of these reasons, simple cholecystectomy is inadequate for T2 or greater tumors. When larger anatomic hepatic resections have been performed in patients with T2 tumors, it has increased the 5-year survival from 25% to 40% after simple cholecystectomy to 70% to 100% after radical resection.^{11,29–31,36–40}

For T3 and T4 lesions, there is a high likelihood of intraperitoneal and hematogenous spread and significant morbidity from the radical procedures that are often necessary for excision of local disease. Recent series, however, support an aggressive approach to resection of these large tumors, particularly if no indication of nodal involvement is found (Table 62.3). For T3 and resectable T4 tumors, a minimal resection includes segments 4b and 5, and in many cases an extended right hepatectomy (segments IV, V, VI, VII, and VIII) may be necessary to obtain complete resection. With aggressive resection, long-term

survival can be achieved even for patients with these more advanced tumors.^{11,12,30,31,34,41}

Surgical exploration should be performed for all patients without medical contraindications. If a T1 tumor is suspected, a cholecystectomy and biopsy of regional nodes should be performed after thorough examination of the abdominal cavity for any signs of tumor dissemination. The pathology and depth of penetration should be confirmed by frozen section, and the procedure terminated if a T1 tumor with negative margins is confirmed. For T2 lesions, either a radical cholecystectomy (wedge resection of the hepatic bed) or a segment IVb and V resection with lymphadenectomy should be performed.¹¹ For T3 lesions, a segment IVb and V resection or extended right hepatectomy is performed. Finally, for T4 lesions, a more radical excision of the liver, such as extended right hepatectomy, usually must be performed for adequate tumor clearance.

Tumor location may be important in determining the extent of resection. If the tumor arises in the gallbladder infundibulum, the common bile duct is often involved with tumor, either by direct extension or external invasion of the hepatoduodenal ligament. In this case, an extended liver resection and removal of a portion of the common bile duct (CBD) should be performed. Reconstruction is then performed by Roux-en-Y hepaticojejunostomy. Tumor arising in the fundus of the gallbladder, however, can be treated with limited hepatic resection without excision of the CBD. To clear the lymph nodes in the porta hepatis, complete lymphadenectomy should be performed, skeletonizing the CBD, hepatic artery, and portal vein.

Incidentally or Laparoscopically Discovered Gallbladder Cancer. Gallbladder cancer is often discovered during pathologic examination after cholecystectomy for presumed benign gallstone disease. Because of the popularization of laparoscopic cholecystectomy in the past decade, an increasing number of patients with gallbladder cancer are found incidentally. Patients with T2 or greater tumors and no signs of distant disease should be offered radical resection to eradicate all disease. Even if grossly normal, excision of laparoscopic port sites should also be performed because of the well-documented history of port-site seeding.^{23,36,42,43}

Patients presenting with gallbladder cancers after a recent cholecystectomy pose additional technical challenges. Often postoperative inflammation occurs in the right upper quadrant that hinders distinction of tumor from normal tissue. Bile spillage at the time of the initial operation may result in carcinomatosis.⁴⁴ Determination of ductal or nodal involvement by tumor is always difficult at the time of reoperation. In addition, postoperative fibrosis often encases the right hepatic artery, which crosses behind the bile duct in most patients. Because of

this, during a second operation for incidentally discovered gallbladder cancer, an extended right hepatectomy along with excision of the extrahepatic biliary tree and portal lymphadenectomy is often necessary. This resection allows adequate exposure for lymphadenectomy and greater confidence of a negative margin on the bile duct, and also permits biliary reconstruction to only one side of the liver. The disadvantage is that a large portion of normal liver parenchyma is sacrificed, and consequently, transient postoperative liver dysfunction is common. Although it may be more difficult to curatively resect disease in patients with incidentally discovered gallbladder cancer after laparoscopic cholecystectomy, there is no difference in overall survival between patients with incidentally discovered gallbladder cancer who are submitted to curative resection and those patients who undergo initial curative resection.³⁵

When a patient presents with T1 gallbladder cancer discovered after simple cholecystectomy, the pathology should be reviewed to determine if the entire gallbladder has been removed and if the cystic duct margin is clear of tumor. If the cystic duct margin is positive, the patient requires bile duct excision. If all margins are negative, no further therapy is warranted. If the tumor is proved to be T2 or greater, the patient should undergo reexcision to attempt complete resection if the extent of disease evaluation is negative. Patients with a known or suspected early gallbladder carcinoma should not undergo laparoscopic cholecystectomy. Rather, open exploration and cholecystectomy should be performed.

Adjuvant Therapy

Adjuvant therapy for gallbladder cancer remains a controversial and unproved consideration. Very few randomized trials have been conducted, and those that have are limited because of the number of patients included. Given the relative rarity of these malignancies in the United States, large-scale, randomized trials are feasible only in the context of a multi-institutional or cooperative group setting.

One recent prospective, randomized phase III trial of adjuvant chemotherapy with 5-fluorouracil and mitomycin C versus surgery alone for patients with pancreaticobiliary malignancies having resection found that in the subset of patients with gallbladder cancer ($n = 112$), the 5-year survival rate was significantly better in the adjuvant group (26%) versus the control group (14%).⁴⁶ Similarly, the 5-year disease-free survival rate was 20.3% versus 11.6%, clearly favoring the adjuvantly treated group. This trial suggests that adjuvant chemotherapy may offer benefit for patients with resected gallbladder cancer; however, replication in a larger-scale setting is required before definitive conclusions can be drawn.

Prognosis

The 5-year survival rate for all patients with gallbladder cancer is less than 5% in most series, with a median survival of 6 months. This is primarily because most patients present with unresectable disease. Of those patients undergoing resection, survival is dependent on depth of penetration and nodal status. Nearly 100% survival is reported after simple cholecystectomy for T1 disease, whereas patients with T2 and T3 tumors without nodal disease have a 5-year survival greater than 50%.^{11,12,34,36} Node positivity is an ominous finding, with few series reporting 5-year survivors.

Follow-up after Resection for Gallbladder Cancer

The most common sites of recurrence after resection of gallbladder cancer include carcinomatosis, intrahepatic metastases,

or nodal recurrence in the retroperitoneum. Jaundice is a common sign, but patients with recurrence may also present with ascites caused by carcinomatosis. For most tumors, local recurrence is found synchronously with diffuse intra-abdominal spread. Therefore, surgical treatment of recurrence has little potential for cure. If recurrent disease is found after resection, prognosis is exceedingly poor, with death occurring secondary to biliary sepsis or liver failure within months of diagnosis.

The main goal of follow-up after resection of gallbladder cancer is to provide palliation for symptomatic recurrences. The main symptoms associated with recurrence requiring palliation are pruritus or cholangitis associated with jaundice, or bowel obstruction associated with carcinomatosis. Additional goals of follow-up are to detect benign complications of surgical treatment such as biliary stricture. When jaundice or cholangitis is the presenting symptom of possible recurrence, a nonsurgical palliative approach using percutaneous transhepatic cholangiogram (PTC) and stenting is usually favored unless a benign postsurgical stricture is suspected. Because of the rapid growth of tumor in patients with recurrence, the hospitalization and recovery time from a surgical bypass is usually not justified for recurrences resulting in biliary obstruction.

The routine follow-up of a patient after resection of gallbladder cancer includes office visits every 3 months with physical examination and measurement of liver function tests. Although CA19-9 may be elevated in patients with gallbladder cancer, the sensitivity and specificity are poor⁴⁷ and, thus, should not be used for screening patients for recurrence. Because an asymptomatic recurrence of gallbladder cancer has only limited treatment options, overaggressive use of imaging studies is not warranted. Therefore, the use of imaging studies should be individualized.

Issues for the Future

Clearly, improving our ability to recognize early gallbladder cancer in high-risk geographic areas would have an important impact on outcome in these patients. This will likely require improvements in understanding the sequential molecular changes associated with gallbladder cancer. Other improvements in screening programs in high-risk areas, which could result in prophylactic cholecystectomy, would likely be beneficial.⁴⁸

BILE DUCT CARCINOMA

One of the most technically difficult surgical resections occurs in patients with bile duct tumors arising in the hepatic hilus, named Klatskin tumors, or hilar cholangiocarcinoma. Bile duct cancers can arise at other sites, including within the liver (intrahepatic cholangiocarcinoma) and below the biliary bifurcation but above the pancreas (mid-bile duct cholangiocarcinoma). Distal cholangiocarcinoma involves that portion of the bile duct within the pancreas, which requires pancreaticoduodenectomy. The location of the tumor affects prognosis as well as the potential for curative resection.

Resection of biliary neoplasms, particularly hilar cholangiocarcinoma, often requires radical resections and complex biliary reconstructions that have only recently become safe in routine practice. Surgery may also offer effective palliation for these cancers by providing biliary bypass for jaundiced patients with unresectable tumors. Because disease is often diagnosed late in the course and because complex operative techniques are required for potentially curative resection, these tumors represent one of the greatest challenges for definitive treatment. Adding to this is that there are no proved effective options for adjuvant treatment.

Incidence

The overall incidence of hilar cholangiocarcinoma in the United States is 1.0/100,000 per year, although other geographic regions such as Israel and Japan have higher rates.⁴⁹ The incidence of intrahepatic cholangiocarcinoma in the United States is approximately 0.7/100,000 with a similar mortality. During the last 30 years, it appears that both the incidence and mortality in the United States are increasing.⁵⁰ Most recently, population studies have noted that there has been a trend toward a relative increased incidence of intrahepatic cholangiocarcinoma (ICC) compared to extrahepatic cholangiocarcinoma (ECC).^{1,51,52} Using the Surveillance, Epidemiology and End Results-Medicare databases, Welzel et al.⁵¹ noted HCV infection, chronic nonalcoholic liver disease and obesity, and smoking being associated only with ICC and not ECC, possibly explaining the divergent trends in incidence. Cholangiocarcinomas arise slightly more often in males,⁹ with a male-to-female ratio of 1.3:1 and an average age of 50 to 70 years.

Known risk factors for this disease include primary sclerosing cholangitis, ulcerative colitis, choledochal cysts, and biliary tract infection, either with *Clonorchis* or in chronic typhoid carriers.⁵³ Treating patients with cholangiocarcinoma arising from one of these underlying conditions is challenging.⁵⁴ Some industrial chemicals (e.g., nitrosamines, dioxin, asbestos, and polychlorinated biphenyls) have also been implicated in the pathogenesis of cholangiocarcinoma.⁴⁹ Although there has been some suggestion of an increased risk of cholangiocarcinoma arising after transduodenal sphincteroplasty,⁵⁵ it is difficult to determine if this is caused by the surgical intervention or the underlying disease leading to sphincteroplasty.

Pathology and Staging

Similar to gallbladder cancer, bile duct tumors tend to invade locally. More than 95% of these tumors are adenocarcinomas. They are morphologically described as nodular, which is the most common, scirrhous, diffusely infiltrating, or papillary. Histologic subtypes include acinar, ductular, trabecular, alveolar, and papillary. Papillary tumors appear to have an improved outcome. Much less common types of bile duct tumors include cystadenocarcinomas, hemangioendotheliomas, and mucoepidermoid carcinomas. Perineural invasion is clearly a poor prognostic sign.⁵⁶

In patients with intrahepatic cholangiocarcinoma, negative prognostic signs include vascular invasion, multiple tumors, positive margin, large size, and lymph node metastases.⁵⁷ These tumors can be either sclerotic, masslike lesions, or cystic lesions.

Historically, cholangiocarcinomas have been classified according to their location in the upper (60%), middle (15%–20%), or lower third (15%–20%) of the bile duct. Middle-third lesions arise between the cystic duct and the superior border of the duodenum. Lower-third lesions are found below the superior border of the duodenum but above the ampulla. The problem with this classification is that the anatomic landmarks are somewhat arbitrary and not clinically useful. Most mid–bile duct malignant obstructions are caused by gallbladder cancer. Even when it is truly a mid–bile duct cholangiocarcinoma, very few of these tumors are amenable to treatment by local excision of the bile duct. A more useful classification is to divide these lesions into upper-half or lower-half tumors, based on the location of the cystic duct as it enters the common duct (in the case of normal anatomy). The usefulness of this classification scheme is that it allows the surgeon to delineate whether a hepatic or pancreatic resection will be required for clearance of tumor. The AJCC TNM staging system (seventh edition) for bile duct cancers is described in Tables 62.4A and B.

Other staging systems have been created that attempt to incorporate clinically important indicators of resectability for hilar cholangiocarcinoma that are defined preoperatively, including hepatic lobe atrophy or portal vein involvement.⁵⁸ With the increasing acceptance of major hepatic resection for these tumors, this preoperative staging system attempts to define whether there is ipsilateral involvement alone, because tumors with bilateral extension past the primary biliary radicles are not resectable.

Clinical Findings and Diagnosis

The vast majority of patients with cholangiocarcinoma present with painless jaundice, though mild right upper quadrant pain, pruritus, anorexia, malaise, and weight loss may also be reported. Cholangitis is the presenting symptom in 10% to 30% of patients. Some patients have cancer discovered on evaluation for otherwise asymptomatic elevations of alkaline phosphatase and gamma-glutamyl transferase.

Patients with intrahepatic cholangiocarcinoma are usually asymptomatic. Many patients are found to have a liver tumor present on cross-sectional imaging obtained for other reasons. Many of these patients will present to the surgeon with a biopsy showing adenocarcinoma without a known primary tumor. The standard evaluation in these patients should include tumor markers to rule out an elevated carcinoembryonic antigen (CEA) or α -fetoprotein (AFP); upper and lower endoscopy to evaluate for a gastrointestinal source; CT scan to assess for a primary tumor in the gastrointestinal tract or pancreas; and, in women, a mammogram. If no site of primary disease is found, in most patients, the diagnosis is intrahepatic cholangiocarcinoma.

Various imaging tests are available to assess patients with hilar cholangiocarcinoma. Abdominal ultrasound is noninvasive, easily available, and inexpensive, and thus is commonly used as a first imaging modality. It can establish the level of biliary obstruction and rule out cholelithiasis or choledocholithiasis as the etiology. CT scans frequently reveal dilated intrahepatic biliary ducts with a normal, collapsed gallbladder, and, depending on the level of the tumor, a nondilated or partially dilated extrahepatic biliary tree (Fig. 62.4). In addition, the presence of hilar adenopathy can be assessed. Portal vein patency can be determined with ultrasound or helical CT. In addition, signs of hepatic lobar atrophy should be sought, because this is associated with a high incidence of ipsilateral portal vein involvement by tumor. MRCP offers the potential of evaluating parenchymal, vascular, biliary, and nodal involvement with a single noninvasive examination.^{20–22} Frequently, it is possible to visualize the tumor itself with MRI (Figs. 62.5 and 62.6).

In most centers, direct cholangiography is used to evaluate the extent of biliary involvement and provide palliation for jaundice. Endoscopic retrograde cholangiopancreatography (ERCP) has little role to play in high biliary obstruction because opacification of the proximal biliary tree is difficult. ERCP, however, can be effectively used to image more distal lesions. At the time cholangiography is performed, some authors advocate the routine preoperative placement of biliary drainage catheters to aid in intraoperative identification of the bile ducts.^{59,60} Others have found a higher incidence of infectious complications⁶¹ and mortality,⁶² and a longer hospital stay,⁶³ after preoperative placement of biliary drainage catheters. The difficulty in making the decision regarding preoperative stenting is that many patients are severely symptomatic because of jaundice and pruritus and require palliation, thus if the operation is delayed, many patients require palliation.

In many cases, it is difficult to obtain pathologic confirmation of cholangiocarcinoma except in very advanced cases, even with the use of biliary brushings and cytology obtained at

FIGURE 62.6. Coronal (A) magnetic resonance imaging and magnetic resonance cholangiopancreatography (B) in a patient with hilar cholangiocarcinoma, demonstrating dilated intrahepatic ducts narrowing at the area of obstruction.

the time of direct cholangiography. In most cases, patients are offered surgical therapy based on clinical suspicion and radiographic appearance. In patients with intrahepatic cholangiocarcinoma, cross-sectional imaging with CT scan is usually sufficient. Tumors may be masslike or may have cystic areas.

Surgery

Proximal Cholangiocarcinomas. Untreated, most patients with bile duct cancers die within a year of diagnosis.^{63,64} Surgical excision is the treatment of choice, with no other potentially curative therapy. The immediate causes of death are most commonly hepatic failure or cholangitis related to tumor growth and inadequate drainage of the biliary tree.⁶⁵ Therefore, the objectives of management for patients with cholangiocarcinoma include both complete removal of tumor and adequate biliary drainage. It has become clear over the last three decades that curative treatment for patients with tumors involving the upper half of the bile duct depends on aggressive excision that often requires a major liver resection. Until as recently as one decade ago, treatment of hilar cholangiocarcinomas was associated with mortality as high as 30%.^{66–70} Recently, major improvements in the safety of these operations has been demonstrated, and resection of hilar tumors now results in mortality of less than 10%, even when liver resections are required.^{66,67,69,71}

Assessment of Resectability and Surgical Procedure.

Surgical exploration is often the only means of assessing resectability. Because of the potential morbidity of a laparotomy that has no therapeutic benefit, staging laparoscopy has been advocated to save patients from unnecessary laparotomy. In patients with hilar cholangiocarcinoma, up to 25% will benefit from staging laparoscopy because of detection of occult extrahepatic disease.^{24,28} Laparoscopy is a very sensitive means to detect peritoneal metastases or additional intrahepatic disease through the use of laparoscopic ultrasound but is less sensitive in detecting nodal metastases or locally invasive tumors.²⁴

Hilar cholangiocarcinoma is considered unresectable because of both local factors and metastatic spread. Clearly, patients with disease outside the liver, including most commonly peritoneal and intrahepatic metastases, are not amenable to curative resection. Local factors that make these tumors unresectable include invasion of the main portal vein or both the

right and left portal vein and hepatic arteries and tumor extension into second-order biliary radicals of both right and left hepatic lobes. By contrast, tumors extending into second- or third-order biliary radicles on one side of the liver without vascular involvement can be resected with curative outcome.

The goals of surgical management for cholangiocarcinomas are both eradication of tumor and establishment of adequate biliary drainage. Tumors of the biliary confluence are particularly difficult to treat because symptoms often appear late in the course of disease when the lesion has already involved adjacent structures including the portal vein or adjacent hepatic parenchyma. Complete resection, therefore, requires biliary and hepatic resection and often major vascular reconstruction. It is not surprising, therefore, that in the past the surgical therapy for proximal biliary malignancies consisted mainly of biliary-enteric bypass as palliation for jaundice and cholangitis. The therapeutic approach to hilar cholangiocarcinoma was largely nihilistic, because of difficulty in delineating the extent of disease and the technical challenge of complete resection for such lesions.

Over the last decade, surgical approaches have become more aggressive, as demonstrated by the increasing number of hepatic resections that have been performed for bile duct cancers.^{66–70} Recent improvements in ultrasound, CT, MRI, and angiography have greatly facilitated preoperative diagnoses and staging of cholangiocarcinoma. This has allowed improved patient selection and surgical planning. The location and local extension of tumor dictates the extent of resection, with most lesions requiring an extended right or left hepatectomy for complete excision. Caudate resection is often required because of direct extension into caudate biliary radicles or parenchyma.^{58,69,70} CBD excision and portal lymphadenectomy are also essential for tumor clearance.

Liver Transplantation for Hilar CCA and the Mayo Protocol.

Orthotopic liver transplantation (OLT) was thought to hold promise for patients with hilar CC, because of its ability to achieve adequate margins by complete hepatectomy. Unfortunately, when used as a single treatment modality, results have been poor. Three- and 5-year survival rates have been reported at 25% to 30%.^{73–75} Because of this poor outcome, the Mayo Clinic developed a protocol combining neoadjuvant therapy with liver transplant, based on a strategy initially developed by the University of Nebraska. This protocol uses high-dose neoadjuvant 5-fluorouracil and brachytherapy

followed by liver transplantation.^{72,76} Inclusion criteria include: (i) locally advanced unresectable disease with either positive intraluminal brush cytology, positive intraluminal biopsy, or CA19-9 ≥ 100 in the setting of a radiographic malignant stricture; (ii) primary sclerosing cholangitis with resectable disease, and; (iii) absence of medical contraindications for OLT. Since 2003, biliary aneuploidy as demonstrated by digital image analysis (DIA)⁷⁷ and fluorescent in situ hybridization have been considered equivalent to cytology.⁷⁸ Exclusion criteria include: (i) extrahepatic disease including regional lymph node involvement; (ii) uncontrolled infection; (iii) prior attempt at resection; (iv) prior treatment with radiation or chemotherapy; and (v) previous malignancy within 5 years. In this protocol, patients receive external beam radiotherapy to a target dose of 4,500 cGy with concomitant fluorouracil (5-FU). Following this, transcatheter iridium-192 brachytherapy with a target dose of 2,000 to 3,000 cGy is administered. Thereafter, patients receive oral capecitabine as tolerated until transplantation. It is important that, prior to transplantation, patients undergo a staging laparotomy, at which time biopsy of perihilar lymph nodes as well as any lymph nodes or nodules suspicious for tumor is performed. Only patients with negative staging operations remain eligible for transplantation.⁷²

Thus, patients eligible for OLT under this protocol have locally advanced tumors but no pathologic nodal disease. Furthermore, the prolonged course of neoadjuvant therapy, staging laparotomy, and time on the OLT waiting list provides an opportunity to exclude patients demonstrating disease progression. This highly rigorous selection bias in favor of patients with biologically favorable disease is reflected in the early outcomes published from the Mayo group. In a recent review of 71 patients enrolled in this transplant protocol, only 38 underwent transplantation (38%). These patients were compared to 26 patients (of 54 explored, 48%) who underwent successful resection. When compared to those undergoing resection (some with node-positive disease), patients undergoing transplantation were younger ($p < 0.001$) and more likely to have inflammatory bowel disease ($p < 0.03$) and PSC ($p < 0.001$). It is important that only 58% of patients had histologically proven cancer.

In these highly disparate groups, 5-year survival was 82% after transplantation (38 patients) compared to 21% after

resection of 26 patients ($p = 0.022$).⁷² There were also fewer recurrences in the transplant patients (13% vs. 27%), and recurrences became apparent later after transplantation than after resection (mean 40 months vs. 21 months). Direct comparisons are difficult with this study given the differences between groups. At present, OLT cannot be considered a standard form of therapy for hilar cholangiocarcinoma for patients with resectable disease, but it does offer a potential option for patients with underlying PSC or those with unresectable tumors who fit the rigorous inclusion and exclusion criteria of the protocol.

Prognosis after Resection. Results of major studies on resection of hilar cholangiocarcinoma are summarized in Table 62.5. In patients amenable to curative resection, the median survival is 35 months with a 5-year survival rate of 10% to 30%.^{61,68,69,72–80} Surgical resection provides both improved survival and improved quality of life.^{79,80} The greatest risk factors for recurrence include the presence of positive margins^{79,81} and node-positive tumors.⁸²

Prognosis after Resection for Intrahepatic or Distal Cholangiocarcinoma. In patients with intrahepatic cholangiocarcinoma, expected 3-year survival rates as high as 60% have been reported,^{24,83} with 5-year survival rates of 30% to 45%.⁸⁴ Patients with unresectable disease have a median survival of 12 months.^{85,86} Thus, completely resected intrahepatic cholangiocarcinoma appears to have an improved prognosis over proximal (hilar) cholangiocarcinoma.

Most patients with distal cholangiocarcinomas are definitively managed with pancreaticoduodenectomy (Whipple procedure) to obtain adequate clearance of tumor, because of the intrapancreatic location of the distal CBD. Patients with cholangiocarcinomas arising in the distal bile duct have both an increased resectability rate and improved prognosis over those with hilar cholangiocarcinomas.⁷¹ Patients with resectable distal bile duct cancer have a 5-year survival rate of 30% to 50%.^{84,87} with a decreased survival if nodes are involved with tumor.⁸⁷

Surgical Treatment of Unresectable Cholangiocarcinoma. For patients with unresectable hilar cholangiocarcinomas, significant improvement in quality of life can occur with surgical bypass. Palliative bypass can be performed in several

FIGURE 62.7. Surgical approach to segment III duct. **A:** The bridge of tissue present at the base of the liver is divided. **B:** The ligamentum teres is held superiorly to expose the tissue overlying the segment III duct. **C:** The segment III duct is exposed. **D:** The duct is opened in preparation for anastomosis with a Roux-en-Y jejunal limb. (Courtesy of Dr. L. H. Blumgart.)

ways. A partial excision of the left lateral segment and biliary-enteric anastomosis to the left hepatic duct (Longmire procedure) was used commonly in the past, but more recently surgical techniques have become less complicated and do not require hepatic parenchymal transection. One technique involves biliary decompression through the left duct, approached through the round ligament, a segment III bypass (Fig. 62.7). Opening the bridge of tissue just beneath the ligamentum teres allows access to the duct. In this position, a long anastomosis can be performed from the segment III duct to a jejunal limb because of the horizontal course of the duct in this location. Although less commonly used, the right hepatic duct can be approached at the base of the gallbladder fossa. This is technically more difficult and results in a higher rate of late bypass failure.⁸⁸

Nonoperative palliative biliary decompression can be accomplished with percutaneous or endoscopic stenting, depending on the level of obstruction. Proximal lesions are usually approached percutaneously with placement of expandable stents or drainage catheters (Fig. 62.8). Internal stents result in fewer electrolyte abnormalities and improvement in patient comfort, although morbidity and mortality occurs in up to 30% of patients and stent occlusion is common.⁸⁹⁻⁹¹ There is a significant risk of cholangitis with external and internal drainage, occurring in more than 90% of patients with metallic expandable internal stents in one series.⁹⁰ Bleeding and bile leaks are also frequent complications. More recent techniques (e.g., pho-

todynamic therapy) have been used to palliate patients with biliary obstruction and may hold some promise for the future.⁹²

Because patients with unresectable disease have a short median survival, those whose disease is clearly unresectable on preoperative imaging should undergo percutaneous internal or external drainage. In patients who undergo exploratory surgery and whose disease is found to be unresectable, surgical bypass offers fewer episodes of cholangitis, with an improved quality of life. In some series, surgical bypass for patients with unresectable disease is the only biliary drainage procedure ever required by the patient.

In patients with unresectable distal cholangiocarcinomas, palliation can be achieved with surgical bypass, percutaneous biliary drains, or ERCP-placed stents. The simplest and most effective way to relieve jaundice is usually with an ERCP stent. Although surgical bypass offers improved patency and fewer episodes of cholangitis, the morbidity of the procedure is not warranted in patients with these aggressive tumors.

INTRAHEPATIC CHOLANGIOCARCINOMA

Patients with intrahepatic cholangiocarcinoma typically present with single liver lesions. The procedure of choice is anatomically based hepatic resection. Because these tumors

FIGURE 62.8. A: Percutaneous transhepatic cholangiogram in a patient with hilar cholangiocarcinoma, demonstrating biliary obstruction at the confluence. The patient has previously had placement of internal/external stents for biliary drainage. B: Film demonstrates appearance of wall stents after deployment into the left and right biliary ducts. C: After stenting, the cholangiogram demonstrates adequate biliary drainage, with contrast filling the duodenum.

are frequently asymptomatic, there are fewer issues with palliative management.

Adjuvant Therapy

- 7 To date, no chemotherapeutic regimen has consistently shown activity against cholangiocarcinoma. Many of the issues that pertain to chemotherapy trials in gallbladder cancer are directly relevant to the interpretation of trials for cholangiocarcinomas. Studies performed to date have typically been small, single-institution trials, including patients with both gallbladder and bile duct cancers.⁹³

Although 5-fluorouracil (5-FU)-based chemotherapy is often offered to patients with unresectable disease, the likelihood of response is less than 10%. Capecitabine as a single agent may have some modest activity in cholangiocarcinomas.⁹⁴ When capecitabine was used in combination with gemcitabine in a recent prospective study,⁹⁵ overall survival was 14 months. Gemcitabine and cisplatin combination therapy has also been tested in phase II studies of patients with advanced biliary tract carcinoma.^{47,96,97} Results of these studies demonstrated response rates of 27% to 34.5%, and overall survival of 9.7 to 11 months. The use of mitomycin C and doxorubicin (Adriamycin), in combination with 5-FU, has resulted in combined response rates of less than 30%, with higher toxicity

than 5-FU alone.⁹⁸ There is no proved role for adjuvant chemotherapy in the treatment of cholangiocarcinoma; however, there are recent data to suggest no difference in overall survival (36% vs. 42%, $p = 0.6$) and locoregional recurrence (38% vs. 37%, $p = 0.13$) between patients undergoing RO resections compared with patients with high locoregional recurrence risk who received adjuvant chemoradiation therapy.⁹⁹

In cases of unresectable cholangiocarcinoma, the use of external beam radiation therapy has been explored.^{100–103} To date, no study has clearly demonstrated efficacy for this modality. Anecdotal reports of long-term survivors after external beam radiotherapy show that some individuals may benefit from such treatment, but this must be weighed against the potential complications (e.g., duodenal or bile duct stenosis and duodenitis). The most encouraging results involve use of intraoperative^{101,104} or interstitial radiation.^{90,102,105} Our current practice is to use combined interstitial radiation and external beam radiation in unresectable cases after palliative bypass. In patients whose disease is resected, adjuvant radiotherapy has not been shown to increase quality of life or survival.¹⁰⁶

Follow-up after Resection of Cholangiocarcinoma

The most likely site of recurrence after resection of a hilar cholangiocarcinoma is locally within the bile duct, regional lymph nodes, or liver. Therapy for recurrence is palliative. Surgical reexcision is usually impossible because of the challenging anatomic location and the radical procedures that are required for resection of the primary tumor. Therefore, the goal of follow-up is diagnosis of symptomatic recurrences to direct palliative therapy and diagnosis of benign complications of surgical treatment (e.g., biliary strictures). The main symptoms of recurrence that demand palliation are pruritus or cholangitis associated with jaundice. For biliary drainage to relieve jaundice or cholangitis, either surgical drainage⁹⁰ or drainage by PTC can be effective.¹⁰⁷ Endoscopic drainage has little role in the relief of jaundice in patients who have had Roux-en-Y biliary reconstruction. For limited recurrences, intraluminal brachytherapy¹⁰⁸ or external beam radiotherapy¹⁰⁹ may improve palliation and, potentially, survival.

Routine follow-up consists of office visits every 3 months with physical examination and measurement of liver function tests. Although a rising alkaline phosphatase level is a good indicator of evolving biliary obstruction, patients recovering from liver resection and biliary obstruction can have persistent elevations of alkaline phosphatase. Up to 10% of patients with biliary surgical reconstruction, however, may develop a benign anastomotic stricture. Most patients with recurrence or a benign stricture will present with jaundice or cholangitis. Because there is a low likelihood of effective therapy for recurrences, the routine use of tumor markers is not recommended, although a fair percentage of biliary malignancies will express CEA or CA 19-9. The routine use of imaging studies to follow patients with cholangiocarcinoma after resection should be limited for the same reasons. When patients become symptomatic with jaundice, an abdominal ultrasound should be obtained. Other imaging will usually be dictated by the sonographic findings.

Issues for the Future

The only known curative therapy for intrahepatic and extrahepatic bile duct cancers is surgery. No proven role is seen for adjuvant chemotherapy alone or adjuvant combined chemoradiation, although further studies are needed to fully define the role of these therapies. Continued assessment of new drugs, novel radiosensitizers, and biologic agents is warranted. A

better understanding of the molecular pathogenesis and genetics of bile duct cancers may lead to new therapeutic and ultimately preventive strategies for high-risk populations.

BENIGN GALLBLADDER NEOPLASMS

Incidence

Benign tumors of the biliary tract are rare, but have been reported more frequently as imaging modalities (e.g., ultrasound and CT scan) have come into widespread and frequent use. In patients undergoing cholecystectomy, the reported incidence of benign gallbladder tumors is less than 3%.

Pathology

Polyps and Pseudotumors. Benign gallbladder tumors are most frequently polyps or polypoid lesions. The incidence of polyps in asymptomatic patients is about 5%.² Cholesterol polyps (cholesterolosis), accounting for half of all gallbladder polypoid lesions,¹¹⁰ result from epithelium-covered, cholesterol-laden macrophages in the lamina propria. These lesions are likely a result of an error in cholesterol metabolism. They extend from the mucosa on a narrow stalk, grossly appearing as yellow spots on the mucosal surface. Nearly all are multiple, and most are less than 10 mm in size.^{6,110,111} When a polyp is pedunculated, it is benign in most cases; alternatively, sessile “polyps” are more often malignant (Fig. 62.9).¹¹¹ Inflammatory polyps result from chronic inflammation and extend by a narrow vascularized stalk into the gallbladder lumen. None of these lesions are considered premalignant, although isolated cases of cholesterolosis associated with in situ carcinoma have been reported.¹¹²

Adenomas. Gallbladder adenomas are found infrequently. They may be tubular or papillary, both arising from the epithelial layer of the gallbladder. Multiple papillary adenomas, or papillomas, are called *papillomatosis*. A direct association between benign adenoma, adenoma containing carcinoma in situ, and invasive carcinoma has been demonstrated; thus

FIGURE 62.9. T₂-weighted magnetic resonance imaging scan showing a sessile polyp within the gallbladder (arrow) that was malignant on histologic examination.

these lesions are considered premalignant.¹¹³ Malignant transformation, however, has only rarely been reported, primarily from large adenomas. In one series, all benign adenomas were less than 12 mm in diameter, whereas the adenomas with cancerous foci were greater than 12 mm.¹¹⁴

Adenomyomatosis. Adenomyomatosis of the gallbladder is characterized by localized or diffuse hyperplastic extensions of the mucosa into, and often beyond, a hypertrophied gallbladder muscular layer. Hyperplasia occurs at outpouchings of the mucosa of the gallbladder through the wall (Rokitansky-Aschoff sinuses) and through the crypts of Luschka. This can result in focal thickening of the gallbladder wall, resembling gallbladder adenocarcinoma. The etiology is unknown. This lesion may be premalignant, because cases of adenocarcinoma arising in or near adenomyomatosis have been reported,^{114,115} but this relationship is unclear.

Other Benign Gallbladder Tumors. Other benign lesions include tumors arising from the tissue of the gallbladder wall, such as leiomyomas, lipomas, hemangiomas, granular cell tumors, and heterotopic tissue, including gastric, pancreatic, or intestinal epithelium.

Clinical Findings

Patients with benign gallbladder tumors typically present with symptoms consistent with choledocholithiasis, including right upper quadrant pain, fatty food intolerance, and nausea. Many benign gallbladder lesions are also discovered incidentally after elective cholecystectomy. Therefore, symptoms caused by benign lesions are difficult to separate from those caused by gallstones. Most lesions, however, are asymptomatic and are discovered incidentally during imaging for other abdominal conditions.

Diagnosis

Diagnosis of benign gallbladder polyps is usually made when an ultrasound study is obtained to evaluate a patient for symptoms consistent with gallstones. On ultrasound, a filling defect that does not change with position is likely a polyp or carcinoma and not a gallstone. Cholesterol polyps are typically small, submucosal, multiple, and hyperechoic on ultrasound because of their high cholesterol content. Other than this typical appearance and the fact that malignant polyps are usually more than 1 cm in size,^{6,110,111} it is difficult to differentiate benign from malignant polyps.

Both intravenous contrast-enhanced and unenhanced CT may be important in distinguishing benign from malignant polyps. In a recent series examining 31 polypoid lesions of the gallbladder, contrast-enhanced CT detected all of the lesions. Benign polyps were not visualized with unenhanced CT, unlike neoplastic tumors, thus improving the ability to distinguish these lesions when both enhanced and unenhanced CT scans were obtained.⁶ Endoscopic ultrasound has also been used to image these lesions, and may be more accurate than transabdominal ultrasound in differentiating benign from malignant tumors.¹⁷

Treatment

Large polyps, greater than 10 mm, have the greatest malignant potential.^{6,110,111} Without evidence of invasion or metastatic disease, however, no radiologic test can reliably differentiate benign from malignant lesions. Therefore, if large (>1 cm) polyps are present, even in asymptomatic patients without stones, cholecystectomy is warranted.¹⁰⁸ Smaller pedunculated lesions with the gross characteristics of a benign cholesterol

polyp may be observed and resected only if symptomatic. Although these lesions have routinely been followed with ultrasound, a recent prospective study suggested that polyps smaller than 1 cm do not progress to carcinoma.¹¹⁶ Cholecystectomy, however, is still considered the standard of care if there is any increase in size.

BENIGN BILE DUCT NEOPLASMS

Incidence

Benign bile duct tumors, at times clinically resembling hilar cholangiocarcinoma, are less common, occurring in less than 1% of patients.¹

Pathology

Attesting to the rarity of these lesions, only two cases of benign extrahepatic bile duct disease occurred in 4,200 biliary tract operations in one institution.¹¹⁷ The most common benign tumors of the extrahepatic biliary tree arise from the glandular epithelium lining the ducts; about two thirds of benign tumors are polyps, adenomatous papilloma, or bile duct adenomas. Most are found in the periaampullary region, but they can be distributed throughout the entire biliary tree (Fig. 62.10). Multiple papillomas also have been reported throughout the intrahepatic and extrahepatic biliary tree, termed *multiple biliary papillomatosis*. Although local recurrence and progression to death from obstructive jaundice and cholangitis occur frequently in these rare cases, these tumors have little, if any, malignant potential. Other benign tumors (e.g., cystadenoma, granular cell myoblastoma, leiomyoma, and heterotopic tissue) have also been reported.

One condition that deserves consideration is the case of “malignant masquerade,” an inflammatory, fibrotic lesion clinically resembling hilar cholangiocarcinoma, but pathologically consisting only of extensive fibrosis and inflammatory cells without evidence of dysplasia or preneoplastic change.^{118–120} In patients being considered for palliative treatment alone with presumed hilar cholangiocarcinoma, it is essential to obtain a tissue diagnosis. It is inappropriate to treat benign lesions by

FIGURE 62.10. Distribution of papillomas and adenomas of the biliary tree. The ampulla and common bile duct are the most frequent sites.

percutaneous stenting because of the excellent outcome after resection of these lesions.

Clinical Findings

Biliary obstruction, with resultant jaundice or cholangitis, is frequently the presenting symptom in patients with benign bile duct tumors. Symptoms may also include epigastric pain or nausea. Because these tumors are indolent, symptoms may be intermittent or gradually progressive.

Diagnosis

Because of the presence of jaundice, benign bile duct tumors are usually initially evaluated with ultrasound. Many patients then undergo ERCP or PTC and CT scan. A diagnosis of malignant masquerade should be suspected in patients with mass lesions that resemble hilar cholangiocarcinomas, but without lobar atrophy or portal vein involvement.

Treatment

Resection and reconstruction are performed to relieve jaundice and cholangitis. The preferred reconstruction is a Roux-en-Y choledochojejunostomy to decrease the risk of postoperative biliary stricture or recurrent cholangitis.

CHAPTER 63 ■ COLONIC AND RECTAL ANATOMY AND PHYSIOLOGY

ELIZABETH C. WICK

KEY POINTS

- 1 The mesorectum is invested by the fascia propria of the rectum.
- 2 The ileocolic branch of the superior mesenteric artery supplies the right colon and part of the transverse colon.
- 3 The inferior mesenteric artery supplies part of the transverse colon, sigmoid colon, and rectum.
- 4 The inguinal lymph nodes drain the lymphatics from the anal canal below the dentate line.
- 5 The colon has 10^{13} bacteria, which promote mucosal immunity, help digest complex nutrients, and protect against pathogenic organisms.
- 6 Alterations in the colonic flora have been associated with inflammatory bowel disease and colorectal cancer.
- 7 Constipation is one of the most common conditions treated by physicians, but only rarely is it due to colonic inertia.
- 8 During postoperative ileus, the stomach recovers after 1 to 2 days, the small bowel after 1 day, and the colon after 3 days.
- 9 Thoracic epidural use after colorectal surgery can shorten postoperative ileus.

EMBRYOLOGY OF THE COLON AND RECTUM

The primitive gut is derived from endoderm and begins to form during the third to fourth weeks of gestation. It is divided into three segments: foregut, midgut, and hindgut. The midgut gives rise to the small intestine distal to the ampulla of Vater, the cecum and appendix, the ascending colon, and the right half to two thirds of the transverse colon, all of which receive blood supply from the superior mesenteric artery. During the sixth gestational week, the midgut herniates from the abdominal cavity into the extraembryonic coelom, undergoes a 270-degree counterclockwise rotation around the superior mesenteric artery, and then returns to the abdominal cavity at 10 weeks' gestation. The hindgut gives rise to the distal one third of the transverse colon, descending and sigmoid colon, rectum, and upper portion of the anal canal, all of which receive blood from the inferior mesenteric artery. The terminal end of the hindgut is the endoderm-lined pouch termed the *cloaca*. During development, the cloaca is partitioned by the urorectal septum into the rectum and upper anal canal and urogenital sinus. Ultimately, the distal anal canal arises from canalization of the ectoderm. The pectineal or dentate line marks the junction between tissue derived from endoderm and ectoderm in the anal canal.

ANATOMY OF THE COLON AND RECTUM

On average, the colon is 150 cm long. Characteristics unique to the colon are (a) taeniae coli, (b) haustra, and (c) appendices epiploicae. There are three taeniae (anterior, posterior medial, and posterior lateral), which are condensations of the outer longitudinal muscle layer in the colon. The taeniae originate at the base of the appendix, course along the

length of the colon, and then converge at the rectosigmoid junction. The haustra are pockets of colon wall, between the taeniae, that result from the fact that the length of the taeniae is one sixth of the colon length.¹ The epiploicae appendices are fat appendages seen on the colonic serosa. The colon consists of five layers: mucosa, submucosa, circular muscle layer, longitudinal muscle layer, and serosa (Fig. 63.1). Microscopically, the colonic mucosa is a columnar epithelium marked by crypts and goblet cells. Unlike the small intestine, the columnar epithelium of the colon and rectum does not have villi.

The colon begins in the right lower quadrant with the cecum. The cecum extends approximately 6 to 8 cm below the ileocecal valve (where the terminal ileum enters the posteromedial aspect of the cecum) (Fig. 63.2). The cecum is the widest portion of the colon (7.5 to 8.5 cm in diameter) and has the thinnest wall. The appendix originates from the lowest portion of the cecum and can be readily identified by following the converging taeniae. In 85% to 95% of people, the appendix lies posteromedial to the cecum, in line with the terminal ileum, but the position can vary, with the most frequent variants being retrocecal, pelvic, and retroileal.² During colonoscopy, visualization of the appendiceal orifice is one of the landmarks required in a complete colonic exam. From the cecum, the right colon ascends to the hepatic flexure (approximately 15 cm). The hepatic flexure is anterior to the inferior pole of the right kidney and overlies the second portion of the duodenum. The hepatic flexure is marked by medial, anterior, and downward angulation of the colon. When the right colon is mobilized during a colectomy, care must be taken to avoid injury to the underlying duodenum. Only the anterior surface of the right colon is invested with peritoneum; laterally, the white line of Toldt marks the extent of the peritoneal covering and serves as an important landmark during surgical mobilization of the colon.

The transverse colon stretches from the hepatic flexure to the splenic flexure and is the longest segment of colon (between 30 and 60 cm). The transverse colon is suspended

FIGURE 63.1. Layers of the colonic wall.

by the transverse mesocolon and is completely intraperitoneal. It is the most mobile portion of the colon. The greater omentum descends from the greater curve of the stomach in front of the transverse colon and then ascends to attach to the transverse colon on its anterosuperior edge. The splenic flexure is situated high in the left upper quadrant, more cephalad than the hepatic flexure. The flexure lies anterior to the mid-left kidney and abuts the lower pole of the spleen. There are attachments from the colon to the diaphragm and spleen (phrenocolic and splenocolic ligaments) and these must be carefully divided during mobilization of the splenic flexure to avoid splenic injury. The descending colon is approximately 25 cm long and courses from the splenic flexure to its junction with the sigmoid colon at the pelvic brim. It lies anterior to the left kidney

and, like the right colon, the anterior, lateral, and medial portions of the descending colon are covered by peritoneum.

The sigmoid colon extends from the pelvic brim to the sacral promontory, where it continues as the rectum and generally measures 30 to 40 cm in length. The rectosigmoid junction is marked by the convergence of the colonic taenia. The sigmoid colon is extremely mobile and has a generous mesentery that extends along the pelvic brim from the iliac fossa across the sacroiliac joint to the second or third sacral segment. Because of its mobile mesentery, the sigmoid colon can twist and cause an obstruction, termed *sigmoid volvulus*. The left ureter runs in the intersigmoid fossa. When the sigmoid colon is being mobilized, the left ureter should be identified to avoid inadvertent injury. Preoperative placement of urinary stents can be useful for locating the ureter intraoperatively in complex, reoperative pelvic surgery.

The rectum, which is 12 to 15 cm long, begins at the level of the sacral promontory and extends to the anorectal ring. The rectum proceeds posterior and caudal along the curvature of the sacrum and coccyx, passing through the levator ani muscles, at which point it turns abruptly caudal and posterior, becoming the anal canal. Anterior to the rectum are the uterine cervix and posterior vaginal wall in women, and the bladder and prostate in men. Posteriorly, the rectum occupies the sacral concavity where the median sacral vessels, presacral veins, and sacral nerves run, all of which are invested in the presacral fascia. The rectum is marked by three curves that correspond to the valves of Houston. The valves are only visible from the lumen and separate the lower third, middle third, and upper third of the rectum, important landmarks when the location of a rectal abnormality is established endoscopically (the lower rectal valve is at 7 to 8 cm from the anal verge, middle rectal valve at 9 to 11 cm, and upper rectal valve at 12 to 13 cm).³ The anterior and lateral surfaces of the upper third of the rectum are intraperitoneal, whereas only the anterior surface of the middle third of the rectum is intraperitoneal in location. The lower third of the rectum is entirely extraperitoneal. The mesorectum is the term used to describe the areolar tissue surrounding the rectum that contains nerves, lymphatics, and terminal branches of the superior hemorrhoidal branch of the inferior mesenteric artery. Although it invests the rectum circumferentially, the mesorectum is most prominent posterior to the rectum. It is invested by the fascia propria of

FIGURE 63.2. General anatomic components of the colon.

FIGURE 63.3. Fascial relationships of the pelvis. (Reproduced with permission from Fascial relationships of the pelvis. In: Corman ML, ed. *Colon & Rectal Surgery*, 5th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2004:8, Fig. 1-6.)

the rectum, a continuation of the parietal endopelvic fascia (Fig. 63.3). A total mesorectal excision entails removal of the entire rectum without violating the fascia propria of the rectum. This is accomplished by mobilizing the rectum using the plane between the fascia propria of the rectum and the presacral fascia.

The surgical anal canal begins at the anorectal ring or levator ani muscles and extends to the anal verge. It measures 2 to 4 cm and is usually longer in men than in women. The internal anal sphincter (continuation of the outer longitudinal muscle of the rectal wall) and the external anal sphincter (continuation of the puborectalis muscle) encircle the anal canal and control fecal continence. The dentate line marks the transition between the columnar epithelium of the intestine and the squamous epithelium of the anal canal.

Arterial Blood Supply

- 2 The superior mesenteric artery arises from the aorta, runs posterior to the pancreas, and passes anterior to the third portion of the duodenum (Fig. 63.4). In addition to supplying the small bowel through jejunal and ileal branches, the superior mesenteric artery gives rise to the ileocolic, right colic, and middle colic branches that supply the cecum, ascending colon, and proximal transverse colon. The right colic arterial anatomy is particularly variable and can be absent or arise from the ileocolic or the superior mesenteric artery. The middle colic artery has a right and left branch that supply the hepatic flexure and the right portion of the transverse colon, while the left branch supplies the left portion of the transverse colon.
- 3 The inferior mesenteric artery arises from the anterior surface of the aorta, typically 3 to 4 cm above the aortic bifurcation, and supplies the distal transverse colon, descending colon, sigmoid colon, and upper rectum. The inferior mesenteric artery gives rise to the left colic artery and sigmoidal branches, then continues in the sigmoid mesentery, and after crossing the left iliac vessels, is renamed the superior hemorrhoidal artery. The supe-

rior hemorrhoidal artery descends behind the rectum and splits into right and left branches in the mesorectum. The middle and inferior hemorrhoidal arteries arise from the hypogastric arteries and supply the distal two thirds of the rectum. The presence of the middle rectal artery, in particular, can be variable. A series of arterial arcades along the mesenteric border of the entire colon, known as the *marginal artery of Drummond*, connect the superior mesenteric and inferior mesenteric arterial systems. The marginal artery may be attenuated or absent at the distal transverse colon/splenic flexure, the delineation between the midgut and hindgut, and thus ischemic colitis most commonly affects this region.

Venous Drainage

The veins that drain the large intestine bear the same terminology and follow a course similar to that of their corresponding arteries (Fig. 63.5). The veins from the right colon and transverse colon, along with the veins draining the small intestine, drain into the superior mesenteric vein. The superior mesenteric vein runs slightly anterior to and to the right of the superior mesenteric artery. The superior mesenteric vein courses beneath the neck of the pancreas, where it joins with the splenic vein to form the portal vein. The inferior mesenteric vein drains blood from the left colon, sigmoid colon, rectum, and superior anal canal. The inferior mesenteric vein ascends over the psoas muscle in a retroperitoneal plane. The vein courses under the body of the pancreas to drain into the splenic vein. During an anterior resection of the rectum, division of the inferior mesenteric vein at the inferior border of the pancreas can provide additional mobility of the left colon to facilitate a coloanal anastomosis. The superior and middle hemorrhoidal veins drain blood from the rectum into the portal system via the inferior mesenteric vein. The inferior hemorrhoidal veins drain blood from the lower rectum and anal canal into the systemic venous circulation via the internal iliac veins. In the setting of portal hypertension,

FIGURE 63.4. Arterial blood supply of the colon.

FIGURE 63.5. Venous drainage of the colon by the portal vein.

the superior, middle, and inferior hemorrhoidal veins interact to shunt venous blood from the portal system into the systemic circulation.

Lymphatic Drainage

- 4 Lymphatic drainage generally follows the arterial blood supply of the colon and rectum. In the anal canal, lesions above the dentate line drain into the inferior mesenteric lymph nodes. Lesions below the dentate line drain into the internal iliac lymph nodes, but can also drain into the inferior mesenteric lymph nodes.

Neural Components

The colon possesses extrinsic and intrinsic (enteric) neuronal systems. The extrinsic system consists of sympathetic and parasympathetic nerves that inhibit or stimulate colonic peristalsis, respectively. The sympathetic innervation to the right colon originates from the lower thoracic segments of the spinal cord and travels in the thoracic splanchnic nerves to the celiac and superior mesenteric plexuses. Postganglionic fibers emerge from here and course along the superior mesenteric artery and its branches to the right side of the colon. The parasympathetic nerves originate from the right vagus nerve and travel along with the sympathetic nerves to the right side of the colon. The left side of the colon and the rectum receive sympathetic fibers that arise from L1 through L3 segments of the spinal cord. The parasympathetic supply to the left side of the colon and the rectum comes from S2 through S4 spinal cord segments.

The intrinsic, or enteric, nervous system consists of two groups of plexuses that are identified by their location within the colon wall. This system can function independently of the central nervous system and controls motility and exocrine and endocrine functions of the gut, and is involved in intestinal immune regulation and inflammatory responses. The Meissner plexus is located in the submucosa between the muscularis mucosae and the circular muscle of the muscularis propria and is important in secretory control. The myenteric plexus, also known as the *Auerbach plexus*, is located between the inner circular muscle and outer longitudinal muscle layers of the colon and primarily controls intestinal motility.⁴

PHYSIOLOGY

Absorption

The colon absorbs water, sodium, and chloride and secretes potassium and bicarbonate. The physiologic control of colonic water and electrolyte transport requires careful integration of neural, endocrine, and paracrine components. Although colonic epithelium does not actively absorb glucose or amino acids as the small-intestinal epithelium does, the colon does absorb short-chain fatty acids and vitamins that are produced by bacterial breakdown of nonabsorbed sugars and amino acids. These short-chain fatty acids, which include acetate, butyrate, and propionate, are absorbed in a concentration-dependent fashion. They are a major energy substrate for colonic epithelial cells and represent the major fecal anions.⁵

Approximately 1,500 mL of ileal effluent reaches the cecum in a 24-hour period, 90% of which is reabsorbed in the colon; 100 to 150 mL of water remains in stool. The colon has a tremendous capacity that allows it to absorb as much as 5 to 6 L of water within a 24-hour period. When colonic capacity is exceeded, diarrhea results.⁶ Normally formed feces consist of

70% water and 30% solid material. Almost half of the solid material is made up of bacteria and the other half is composed of undigested food material and desquamated epithelium. Water absorption in the colon is a passive process that depends primarily on the osmotic gradient established by the active transport of sodium across the colonic epithelium. The composition of ileal effluent and luminal flow rates also play an important role in water absorption. Upsetting the balance of these three factors results in diarrhea. The absorptive capacity is not the same throughout each segment of the colon. Salt and water absorption is greatest in the right colon. Patients undergoing a right hemicolectomy should therefore be counseled preoperatively that they may experience loose bowel movements in the early postoperative period. Patients should also be reassured that this will resolve with time as the remaining colon adapts.

Sodium absorption by the colonic epithelium is an active cellular transport process similar to that seen in small-intestinal and renal epithelial cells.⁷ Initially, sodium absorption involves the passive movement of sodium across the apical membrane into the mucosal cell down an electrochemical gradient. To maintain an adequate electrochemical gradient, intracellular sodium is removed from the cell into the interstitial space in exchange for potassium. This is an energy-dependent process that is controlled by $\text{Na}^+\text{-K}^+\text{-adenosine triphosphatase (ATPase)}$. Mineralocorticoids (predominantly aldosterone) and glucocorticoids accelerate sodium absorption and potassium excretion in the colon by increasing $\text{Na}^+\text{-K}^+\text{-ATPase}$ activity.⁸ Potassium movement into the colonic lumen is primarily a passive process that depends on the electrochemical gradient generated by the active transport of sodium across colonic epithelial cells. Chloride absorption in the colon is generally thought to be an energy-independent process that is associated with reciprocal exchange for bicarbonate at the luminal border of the mucosal cell.⁹

Colonic Flora

- 5 The bacterial flora of the colon is established soon after birth and depends in large part on dietary and environmental factors. The colon is populated by approximately 10^{13} commensal bacteria.¹⁰ The vast majority of the normal colonic flora consists of anaerobic bacteria, with *Bacteroides* species being most prevalent, particularly *B. fragilis*.¹¹ Aerobic colonic bacteria are mainly coliforms and enterococci, with *Escherichia coli* being the most predominant coliform. The colonic flora is important for (a) digestion and absorption of complex macromolecules, (b) protecting the colon against invasion by noncommensal bacteria, and (c) development of mucosal immunity. Fermentation of carbohydrates generates short-chain fatty acids, including butyrate, which is the primary nutrient for the colonic mucosa. Colonic bacteria also produce certain vitamins, such as vitamin K and B_{12} , which are absorbed by the host. The enterohepatic circulation of bilirubin and bile acids depends on bacterial enzymes produced by fecal flora. The degradation of bile pigments by colonic bacteria gives stool its characteristic brown color. Colonic bacteria also play an important role in preventing infection by controlling the growth of potentially pathogenic bacteria such as *Clostridium difficile*.

- 6 Host and colonic flora have a mutualistic relationship; however, disturbances of this coexistence can lead to human disease.¹² Dysregulation of the flora has been implicated in the pathogenesis of inflammatory bowel disease and, to a lesser extent, colorectal cancer. In animal studies, mice with certain immune deficiencies that make them prone to colitis fail to develop colitis when raised under germ-free conditions. Analysis of the microbiota of patients with inflammatory bowel disease revealed markedly different flora compositions in ulcerative colitis, Crohn disease, and healthy control patients. Similarly, certain genetically altered mice

with a propensity to develop colorectal cancer fail to develop tumors in germ-free conditions. Although studies of human flora and colorectal cancer are limited, preliminary studies have raised interest in modulating the colonic flora as a way to treat and/or prevent colitis and other diseases of the colon.

Colonic Motility

Motor activity varies greatly throughout the colon. There are two patterns of colonic motility: segmental contractions, which are single or clustered contractions, and propagated activity, which is either high-amplitude propagated contractions (HAPCs) or low-amplitude propagated contractions (LAPCs). *Segmental contractions* are intermittent contractions of the longitudinal and circular muscles that result in the segmented appearance of the colon.¹³ These contractions propel luminal contents in a back-and-forth pattern over short distances, slowing aboral transit and allowing for water reabsorption.¹⁴ *Propagated activity* consists of strong, propulsive contractions of the smooth muscle that involve a long segment of colon.¹⁵ The LAPCs move luminal contents forward at a rate of 0.5 to 1.0 cm/s and typically last for 20 to 30 seconds.¹³ HAPCs occur three to four times per day, primarily after awakening, exercise, and after meals.

The orderly progression of colonic luminal contents from cecum to anus requires the coordination of smooth muscle contractions. Calcium-dependent cyclic depolarization and repolarization of the colonic smooth muscle cell membrane generates a basic electrical pattern of slow-wave activity. This activity allows each smooth muscle cell to control its own contraction and to couple with adjacent smooth muscle cells.¹⁶ The extrinsic (autonomic) and intrinsic (enteric) neuronal systems also interact to influence colonic motility.

Defecation

As the fecal mass enters the rectum, the internal anal sphincter relaxes while the external anal sphincter contracts to maintain continence. Distention of the rectum in this setting is the primary stimulus for defecation to begin. At this point, the urge to defecate may be suppressed by conscious contraction of the external anal sphincter. Receptive relaxation of the rectal ampulla accommodates the fecal mass and the urge to defecate passes unless the volume of feces is extremely large or the sphincter mechanism is impaired. If the subject voluntarily accedes to the urge to defecate, a Valsalva maneuver occurs, which increases the intra-abdominal pressure to overcome the resistance of the external anal sphincter. Relaxation of the pelvic muscles causes the pelvic floor to descend and the anorectal angle to straighten. Conscious inhibition of the external anal sphincter then allows passage of the feces. On completion, the pelvic floor returns to its resting position and the anal sphincter muscles return to their resting activity, closing the anal canal. Under normal circumstances, this process occurs once every 24 hours; however, the interval between bowel movements may vary between 8 and 12 hours and 2 to 3 days in normal subjects. The frequency of defecation is influenced by multiple environmental and dietary factors.

DISORDERS OF COLONIC MOTILITY

Constipation

Constipation is common and may affect up to 15% of people, but only a portion of affected individuals seek medical

TABLE 63.1

DIAGNOSIS

ROME III CRITERIA FOR THE DIAGNOSIS OF CONSTIPATION

Two or more of the following:

- Straining in >25% of bowel movements
- Incomplete evacuation of the rectum in >25% of bowel movements
- Hard stool consistency in >25% of bowel movements
- Three or fewer bowel movements weekly
- Manual maneuvers in >25% of bowel movements
- Sensation of anorectal obstruction in >25% of bowel movements

Do not meet the criteria for irritable bowel syndrome

Loose stools rarely present without the use of laxatives

7 help.¹⁷ Colorectal surgeons, gastroenterologists, gynecologists, and family medicine physicians are frequently called upon to treat constipation.¹⁸ To evaluate constipation, the clinician must ask focused questions about bowel function. Constipation can mean infrequent bowel movements, straining, or hard stools. The Rome criteria were developed to help standardize the diagnosis (Table 63.1). Constipation can be caused by lifestyle choices, side effects of medications taken for other reasons, medical conditions, structural abnormalities of the colon, pelvic floor dysfunction, and colonic inertia (Table 63.2). Evaluation of the constipated patients includes a thorough history, a physical examination including a rectal exam, and evaluation for sources of pelvic floor dysfunction such as rectocele. Colonoscopy may be necessary to eliminate a structural bowel obstruction as the cause of constipation.

After eliminating medication-related or metabolic causes of constipation and in the absence of systemic symptoms, it may be practical to initiate medical therapy before proceeding with radiologic testing for rare conditions such as colonic dysmotility or pelvic floor dysfunction. The goal of first-line medical therapy is to increase stool bulk and physical activity. Fiber intake should be increased to 20 to 30 g/d. To achieve this recommended daily amount, fiber supplementation with either psyllium or methylcellulose is frequently required. At least eight glasses of water should be ingested daily. Fiber and water intake increases stool bulk, and bulky bowel movements stimulate colonic motility. If fiber, water, and exercise do not relieve constipation, then laxatives should be added to the regimen. Laxatives can be divided into different categories by mechanism of action (Table 63.3). Osmotic laxatives are usually the first-line treatment for severe constipation. Long-term use of laxatives, which irritate the colon, should be avoided, however, because they can actually impair colon function. Melanosis coli, a dark discoloration of the colonic mucosa seen on colonoscopy, is a sign of frequent laxative use.

Some patients whose constipation does not respond to standard medical therapy will be found to have slow-transit constipation or pelvic floor dysfunction, both of which require radiologic studies for diagnosis. The most common technique for evaluating colonic transit is a Sitz marker study (Fig. 63.6). To complete this test, all laxatives must be stopped 48 hours before the study. On day 0, a set number of radiopaque markers are ingested; an abdominal radiograph is obtained on day 1 to

document that the markers were ingested, and again on day 5 to determine if the markers have been expelled. Normally, on day 5, more than 80% of the markers should be evacuated. If more than 20% of the markers remain and they are either clustered in the right colon or evenly distributed throughout the colon, the patient has slow-transit constipation. Outlet obstruction is suggested by clustering of the markers in the sigmoid or rectum. Outlet dysfunction can be further evaluated with defecography, a fluoroscopic study of defecation. Slow-transit constipation is best treated with surgery, and obstructed defecation with biofeedback therapy.

Postoperative Ileus

Postoperative ileus is transient impairment of bowel function after an operation. It is most common in patients after

8 intra-abdominal surgical procedures, particularly colonic operations. Clinically, postoperative ileus is manifested by abdominal distention and delayed passage of flatus and, less frequently, by nausea and vomiting. After an abdominal operation, the colon usually takes 3 to 5 days to recover, whereas the stomach and small bowel resume normal motor function more rapidly (1 to 2 days and 1 day, respectively).¹⁹ In a recent multicenter study, the average length of hospital stay after bowel resection was 6.6 days, with 11.5% of patients requiring a nasogastric tube for ileus.²⁰ Postoperative ileus is multifactorial. Surgical and anesthetic technique, narcotic use, inactivity, and postoperative infectious complications all have been implicated in prolonged ileus. Bowel manipulation has also been suggested to contribute to the development of ileus.²¹ The observation that postoperative ileus is shorter after minimally invasive surgery adds credence to this theory.²² Use of the anesthetic agent halothane, as well as opioid analgesics, can prolong postoperative ileus.¹⁹ After surgery, systemically administered morphine, in addition to binding to μ opioid receptors in the central nervous system and promoting analgesia, binds to peripheral μ opioid receptors in the colon and causes nonpropulsive electrical activity that can prolong ileus.²³

9 Postoperative ileus lengthens hospital stays, and thereby hospital costs. The burgeoning cost of health care has renewed the interest in medications to prevent or shorten postoperative ileus. Research has focused on new pain management strategies that minimize systemic narcotics, and pharmacologic agents to promote intestinal motility. One of the most promising strategies is the use of a thoracic epidural for postoperative analgesia. The thoracic epidural block promotes parasympathetic activity by blunting sympathetic stimulation of the gut. The greatest benefit is seen with epidural infusions of local anesthetic (lidocaine or bupivacaine), as compared to narcotics.¹⁹ Other benefits of using thoracic epidurals in the postoperative period are increased mental acuity and better pain control, both of which promote early mobility, particularly in elderly patients.²⁴ Currently, alvimopan, an oral medication that blocks the μ opioid receptors in the gastrointestinal tract, is the most studied antidote for ileus. A phase III multicenter study of patients who had a bowel resection or hysterectomy found that alvimopan (12 mg before surgery, then twice a day until discharge) decreased hospital stay by 18 hours as compared to placebo.²⁵ With an improved understanding of the molecular basis of intestinal motility, we can expect new, targeted medications for decreasing postoperative ileus in the future.

Irritable Bowel Syndrome

Irritable bowel syndrome is defined as abdominal pain that is not associated with an anatomic abnormality and may or may not be associated with alterations in bowel habits. The causes of this disorder are uncertain. Emotional stress and psychiatric illness have been implicated in the pathogenesis of the disorder and may exacerbate symptoms.²⁶ Physiologic abnormalities have also been demonstrated, as has abnormal colonic motility in response to an ingested meal.²⁷ Altered myoelectric activity and abnormal gut hormone secretion have also been cited as potential causes.

Because no one, clear cause of irritable bowel syndrome has been demonstrated, no specific treatment regimen has been defined for this disorder. Most patients have asymptomatic periods interrupted by intervals of symptoms. The approach to treatment begins with an evaluation of the factors associated with irritable bowel syndrome. Diagnosis and treatment of an underlying psychiatric problem may resolve the patient's symptoms. A detailed dietary history

should also be taken, and factors that contribute to constipation or diarrhea should be adjusted appropriately. If these management strategies are not successful, gradually introducing anticholinergic medications may be helpful. Anticholinergic agents can reduce the rate of myoelectric activity and decrease tonic contractions in the colon, thereby relieving the cramping and bloating that many patients experience. Low doses of tricyclic antidepressants, including imipramine, amitriptyline, and nortriptyline, often decrease or eliminate abdominal symptoms. Constipation is known to be one major side effect of these agents, which may be helpful in patients with irritable bowel syndrome and underlying diarrhea, but a problem in patients with preexisting constipation. The myriad treatment options described for irritable bowel syndrome underscores the poor understanding of this clinical entity.

Colonic Pseudo-obstruction

Colonic pseudo-obstruction, also known as *Ogilvie syndrome*, is massive dilation of the colon without an actual mechanical obstruction. In 1948, Ogilvie described two patients with colonic pseudo-obstruction from malignant infiltration of the celiac plexus that he postulated led to sympathetic inhibition.²⁸ In the intestine, stimulation of the sympathetic nervous system decreases intestinal motility, whereas activation of the parasympathetic nervous system promotes contractility. Colonic pseudo-obstruction results from an imbalance in the autonomic nervous system of the gastrointestinal tract. Various metabolic conditions, pharmacologic agents, and traumatic factors can alter the balance of the intestinal autonomic nervous system and have been associated with colonic pseudo-obstruction.²⁹ The most frequent presenting symptoms are abdominal pain and nausea and vomiting. On physical examination, the abdomen is distended and tympanic and may be mildly tender when palpated. Marked colonic distention present on an abdominal radiograph is the hallmark of the condition (Fig. 63.7). Fever and leukocytosis are rare and should raise the concern for perforation.³⁰ First-line management of colonic pseudo-obstruction is conservative and consists of nasogastric decompression, cessation of oral feedings, correction of fluid and electrolyte imbalances, and avoidance of narcotics and anticholinergics. If abdominal radiographs do not show gas throughout the colon, an abdominal computed tomography scan or a Gastrografin enema should be considered to rule out a mechanical obstruction. With conservative measures, colonic pseudo-obstruction resolves in more than 75% of cases. When the pseudo-obstruction persists for more than 6 days and/or the diameter of the cecum on abdominal radiograph is greater than 12 cm, the risk for cecal perforation increases.^{30,31}

Colonic pseudo-obstruction is most commonly seen in elderly patients who may have other significant medical conditions, so when free perforation occurs, it can be associated with significant morbidity and mortality (up to 40% in one study³²). In patients whose pseudo-obstruction is not responding to conservative therapy but who have no signs of peritonitis, 2.5 mg of neostigmine given intravenously over 2 to 3 minutes has been found to decompress the colon promptly in nearly all patients.^{33,34} Neostigmine is a reversible acetylcholinesterase inhibitor that stimulates the intestinal parasympathetic receptors, promoting colonic motility.³⁵ In a randomized controlled study, the pseudo-obstruction resolved promptly in 10 of 11 patients.³³ If neostigmine fails to decompress the colon, another alternative is decompressive colonoscopy. In one series, 69% of patients had resolution of their pseudo-obstruction after colonoscopy to remove air.³⁵ Surgery is reserved for patients with obvious peritoneal signs or whose pseudo-obstruction has not improved after all forms of nonsurgical therapy. In

FIGURE 63.7. Pseudo-obstruction of the colon (Ogilvie syndrome).

such patients, when the possibility of cecal perforation is high, a cecostomy can be considered.

CHAPTER 64 ■ GASTROINTESTINAL MOTILITY DISORDERS

SANDRA A. TAN AND GEORGE A. SAROSI Jr.

KEY POINTS

- 1 Ileus is defined as impairment in the aboral passage of intestinal contents secondary to a failure of normal intestinal motility in the absence of an obstructing lesion. Ileus is the most common gastrointestinal motility disorder encountered by surgeons.
- 2 Irritable bowel syndrome is a chronic gastrointestinal illness characterized by frequent unexplained abdominal pain associated with bloating and disturbance in normal bowel function.
- 3 Normal esophageal peristalsis interrupted by simultaneous contractions is the hallmark of diffuse esophageal spasm.
- 4 Diabetic gastroparesis may affect 50% of diabetic patients.
- 5 Dumping syndrome is a clinically defined spectrum of symptoms observed after gastric surgery thought to be a consequence of accelerated gastric emptying following vagotomy and bypass or destruction of the pylorus.
- 6 The most common presenting symptom of gallbladder dyskinesia is abdominal pain in the absence of gallstones or other structural cause of right upper quadrant pain.
- 7 The diagnosis of colonic inertia is established in a chronically constipated patient with markedly prolonged colonic transit time in the absence of anorectal dysfunction.
- 8 Acute colonic pseudo-obstruction is a clinical syndrome characterized by massive dilation of the colon in the absence of mechanical obstruction. The syndrome generally develops in ill patients hospitalized initially for other significant medical problems.

Orderly progression of a swallowed food bolus from the mouth through the entire digestive system and expulsion of the residual material remaining after digestion is the normal function of gastrointestinal motility. Loss of normal gastrointestinal motor activity causes failure of major gastrointestinal functions, including absorption of nutrients and fluid and secretion of waste products. Although many acute surgical diseases result in secondary failure of gastrointestinal motor function, the majority of diseases causing primary gastrointestinal motor dysfunction are not surgically treated. Because many primary motility disorders can present in a similar fashion to common surgical diseases, and a few primary motility disorders are surgically treated diseases, surgeons must be familiar with gastrointestinal motility disorders. This chapter provides a broad overview of gastrointestinal motility disorders with a focus on the pathophysiology of motility disturbances.

DISORDERS AFFECTING THE ENTIRE DIGESTIVE TRACT

Ileus

- 1 Ileus is defined as impairment in the aboral passage of intestinal contents secondary to a failure of normal intestinal motility in the absence of an obstructing lesion. Ileus is the most common gastrointestinal motility disorder encountered by surgeons. Broadly defined, there are two major categories of ileus: postoperative ileus and ileus related to metabolic abnormalities, drugs, inflammation, or ischemia (Table 64.1). The most common etiology of ileus is the postsurgical state, as some component of postoperative ileus is associated with essentially all major intra-abdominal procedures and many nonabdominal surgical procedures.¹

Although the pathophysiology of ileus remains incompletely understood, in recent years the basic mechanisms of

postoperative ileus have been elucidated. In the immediate postoperative period, all three functional segments of the gastrointestinal tract, the stomach, small intestine, and colon, display impaired motility characterized by disorganized electrical activity and a lack of coordinated propulsion.² Although all segments of the gastrointestinal tract are affected by ileus in the postoperative period, the duration of the dysmotility varies by segment. Small bowel motility normalizes first, often within a few hours.³ Gastric motility usually returns to normal within 24 to 48 hours, but colonic motility takes 2 to 5 days to normalize, and it is this functional segment that contributes most to the clinical effects of postoperative ileus.^{4,5}

The pathophysiologic mechanisms underlying postoperative ileus are multifactorial. Three major contributing factors are spinal and local sympathetic reflexes, local and systemic inflammatory mediators, and exogenous factors including opioid analgesics and electrolyte disturbances. The role of spinal and sympathetic reflexes in ileus has been investigated in animal models, in which interventions such as spinal cord transection or pharmacologic neuronal depletion have been shown to decrease the duration of postoperative ileus.⁶ These animal observations have been confirmed in human studies, which demonstrate that interruption of gastrointestinal tract spinal reflexes with epidural local anesthetics significantly reduces the duration of postoperative ileus.⁷ Multiple neurotransmitters intrinsic to the enteric nervous system may play a role in regulating gastrointestinal motility in the postoperative period. Nitric oxide, vasoactive intestinal polypeptide (VIP), and substance P reduce intestinal motility and have been linked to postoperative ileus in animal studies.^{8,9} In contrast, both motilin and ghrelin promote motility during the resolution of postoperative ileus in both humans and animals.^{10,11}

Local inflammation and systemic inflammatory mediators play an important role in postoperative ileus. Animal studies have demonstrated that surgical manipulation results in the accumulation of inflammatory cells in the muscular layer of the small intestine and that the degree of inflammation

TABLE 64.1 ETIOLOGY**CAUSES OF ILEUS**

Abdominal surgery
Electrolyte abnormalities
Drugs
Intra-abdominal inflammation
Retroperitoneal trauma or inflammation

correlates with the degree of manipulation. In elegant animal studies, investigators have demonstrated that this infiltrate results in muscular dysfunction and jejunal dysmotility and that the inhibition of leukocyte infiltration reduces ileus.¹² The correlation between intestinal inflammatory cell infiltration and the degree of bowel manipulation may help explain the reduction in postoperative ileus observed with laparoscopic surgical approaches. Elevated serum levels of inflammatory cytokines such as interleukin-1 (IL-1) and IL-6 are seen in the postoperative period and may also be associated with decreased gastrointestinal function.¹³

Opioid analgesics are the mainstay of postoperative pain control and have a powerful influence on gastrointestinal motility through actions on peripheral opioid receptors found throughout the gastrointestinal tract.¹⁴ Opioid analgesics have been shown to directly inhibit gastric, small bowel, and colonic motility, and limited narcotic use reduces postoperative colonic dysmotility in humans.^{15,16} Electrolyte abnormalities are common in patients dependent on intravenous fluids for hydration, and one study has linked hypokalemia with prolonged postoperative ileus and demonstrated resolution of ileus with potassium therapy.¹⁷

Preventing ileus or reducing its duration has enormous potential to reduce health care expenditures and improve patient comfort in the perioperative period. Although no single treatment exists that can eliminate postoperative ileus, there are several interventions that may shorten the duration of this motility disorder. The two most effective interventions are thoracic epidural analgesia with local anesthetics and minimally invasive surgical approaches. Six of eight randomized trials comparing the effects of epidural analgesia to systemic opiates on postoperative ileus demonstrate a statistically significant reduction in the duration of ileus with epidural analgesia, with a typical effect size of 1 to 2 fewer days of ileus.⁷ This effect is observed with epidural local anesthetics but not with epidural narcotics. Laparoscopic surgery appears to reduce the duration of postoperative ileus by reducing the amount of bowel manipulation and intraperitoneal inflammatory response. Four of six randomized trials comparing laparoscopic with open colectomy have shown a significant decrease in postoperative ileus with a typical effect size of 24 hours.⁷

Multiple pharmacologic interventions have been studied including promotility agents such as metoclopramide, erythromycin, and cisapride; adrenergic blockade; parasympathomimetic agents; and opiate antagonists. Of these agents, only cisapride, which is no longer available in the United States, and the peripheral opiate antagonist alvimopan (Entereg) have been shown to reduce the duration of postoperative ileus.¹⁸ Nonpharmacologic measures that show promise in reducing postoperative ileus include early enteral feeding, sham feeding, and gum chewing. These interventions have not been proven to have benefit in large randomized trials; however, meta-analysis of small trials suggests that gum chewing can reduce the duration of postoperative ileus after open colectomy by 1 day.¹⁹ Standard interventions such as early ambulation and nasogastric decompression have no effect or prolong postoper-

ative ileus when careful studies are performed, despite being considered standard of care.²⁰ Multimodality therapy, combining several interventions, shows promise in reducing postoperative ileus, but systematic studies have not yet been performed.

Irritable Bowel Syndrome

2 Irritable bowel syndrome (IBS) is a chronic gastrointestinal illness characterized by frequent unexplained abdominal pain associated with bloating and disturbance in normal bowel function. Although in the strictest sense not a gastrointestinal motility disorder, IBS is associated with many of the symptoms of gastrointestinal motility disorders, and patients with IBS have alterations in gastrointestinal motor function. IBS is a common disorder with an estimated prevalence of 12% in adults in the United States. The peak incidence of the disease is in the second through fifth decades of life, and it is rare in patients older than age 50 years. There is a 2:1 female-to-male predominance.²¹ The combination of abdominal pain in association with constipation, diarrhea, or alternating constipation and diarrhea that does not fit the pattern of a conventional gastrointestinal disorder should lead to consideration of the diagnosis of IBS. No single test can diagnose IBS; rather, the condition is diagnosed by the presence of specific symptoms known as the Rome III criteria (Table 64.2) in the absence of other organic diseases.²²

IBS is characterized by abnormal patterns of small bowel and colon electrical activity known as *discrete clusters of contractions*.²³ Rather than representing a true gastrointestinal motility disorder, these patterns are thought to be an exaggeration of the normal intestinal stress response.²⁴ Patients with IBS also have increased visceral sensitivity to bowel distention, and are more likely to perceive this distention as a noxious stimulus than normal controls.²⁵ This combination of heightened sensitivity associated with an exaggerated intestinal motility response to stress is thought to explain the symptoms of IBS. The cause of the heightened sensitivity to visceral stimulation is not clear, but inflammation triggered by infection, the postoperative state, or perhaps food allergies may play a role.²⁶

The treatment of IBS is directed at symptomatic control. Importantly for surgeons, patients with IBS appear to have higher rates of common surgical procedures such as cholecystectomy, hysterectomy, and appendectomy than patients without the diagnosis of IBS.²⁷ The reasons for this observation are not clear. Three possible explanations include the overlap of IBS symptoms with the symptoms of surgically treated diseases, increased health-seeking behavior in IBS patients, and the ability of postsurgical inflammation to create visceral sensitization.

TABLE 64.2 DIAGNOSIS**ROME III DIAGNOSTIC CRITERIA FOR IRRITABLE BOWEL SYNDROME**

Recurrent abdominal pain or discomfort at least 3 d per month in the last 3 mo associated with two or more of the following:

Improvement with defecation

Onset is associated with a change in stool frequency

Onset is associated with a change in stool appearance

The criteria must be fulfilled for the last 3 mo with symptom onset at least 6 mo prior to diagnosis

Adapted from Longstreth GF, Thompson WG, Chey WD, et al. Functional bowel disorders. *Gastroenterology* 2006;130:1480–1491.

For these reasons, rigorous attention to surgical indications in patients with IBS symptoms is critical.

Dietary modification and teaching patients to more effectively manage stressful life events that trigger symptoms are the usual starting points of therapy. Psychotherapy, including cognitive-behavioral therapy, has been shown to be beneficial. Management of constipation with fiber therapy and diarrhea with antidiarrheal agents is helpful. Antispasmodic agents may reduce pain symptoms, although they do not appear to affect motility disturbances.²¹ Tricyclic antidepressants appear to control motility disturbances in selected patients. This effect is independent from antidepressant actions, as serotonin reuptake inhibitors have not been shown to be effective.²⁸ Two serotonin axis agents, the serotonin-3 receptor antagonist alosetron and the serotonin-4 agonist tegaserod, have been shown to be beneficial in diarrhea-predominant and constipation-predominant IBS, respectively.^{29,30}

DISORDERS AFFECTING SPECIFIC ORGANS

Esophagus

Achalasia. The term *achalasia* is derived from the ancient Greek *chhalasis*, or relaxation; thus *achalasis*, failure to relax. This word describes the characteristic motility disorder of achalasia: failure of the lower esophageal sphincter (LES) to relax.³¹ Hypermotility of the body of the esophagus is usually the initial response to the functional obstruction of the LES, eventually resulting in hypomotility and aperistalsis. When the esophageal body becomes aperistaltic, the viscus becomes a large pouch in which food remains for days with minimal transit to the stomach. Achalasia is a rare disorder, with an incidence in the Western world of 0.5 to 1.1 per 100,000.³² Achalasia can occur at any age, and both sexes are equally affected. Symptoms are the hallmarks of the disease; dysphagia is the predominant symptom, with dysphagia for solid food present in more than 50% of patients and dysphagia for liquids present in two thirds of cases. The combination of dysphagia to both liquids and solids is more suggestive of functional disease rather than anatomic obstruction such as a stricture or tumor. The symptoms of dysphagia typically plateau over time, as patients learn to alleviate symptoms and improve esophageal function with postural maneuvers or other strategies that increase intraesophageal pressure and promote esophageal emptying.

Approximately 50% of achalasia patients complain of chest pain. The relationship of pain to esophageal function is unclear as improvement of esophageal emptying does not necessarily ameliorate pain. Regurgitation occurs in 76% of patients and is associated with aspiration of esophageal contents and pulmonary complications in 10%. Heartburn symptoms are noted in roughly 50% of patients. Weight loss usually occurs late in the course of achalasia. The clinical presentation of achalasia is often subtle in early-stage disease but may be dramatic in the decompensated phases of the disease.³³

A barium swallow study is an appropriate initial test in a patient with suspected achalasia. Abnormal or absent clearance of the barium bolus is seen, particularly in the recumbent position. In achalasia, relaxation of the LES fails to occur with swallowing, causing radiographic findings resembling a “bird’s beak.” In the late phases of the disease, a dilated esophagus is commonly present. An epiphrenic diverticulum proximal to the LES can be seen in this disease. Its size may vary, and its presence may make diagnostic tests difficult. Esophageal manometry reveals failure of the LES to completely relax in more than 85% of patients with achalasia, often associated with aperistalsis of the esophageal body, and is used as an important confirmatory test in the diagnosis of achalasia.³³ Recent work

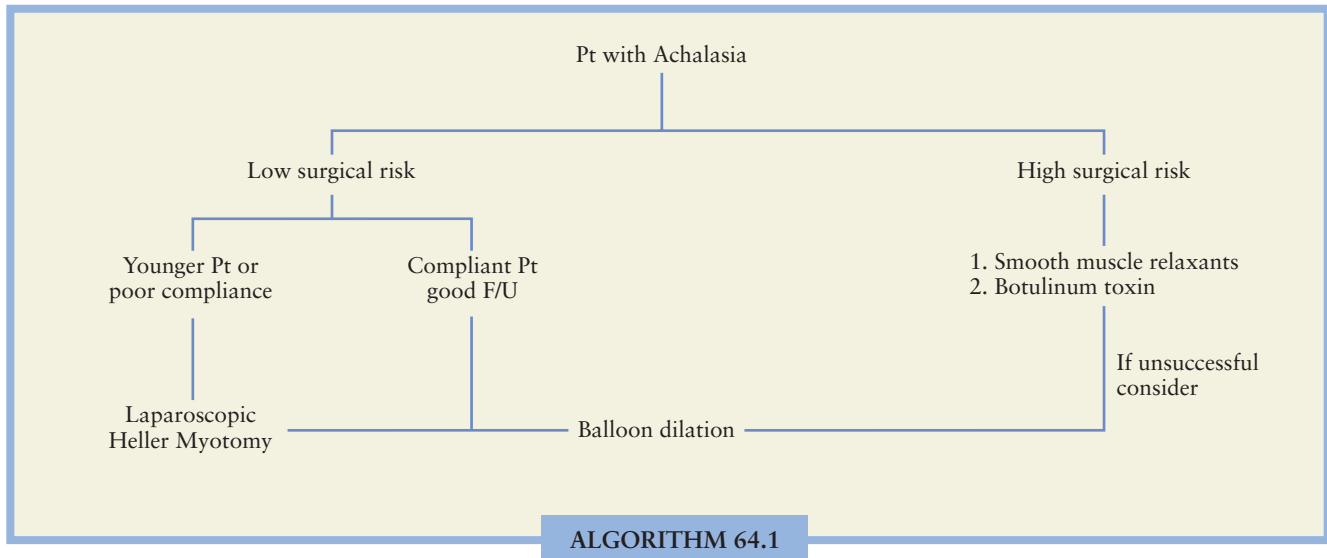

suggests that high-resolution esophageal manometry may be an even more sensitive test for achalasia than traditional manometry.³⁴

The etiology of primary achalasia is not understood; several mechanisms have been postulated including immunologic, infectious, and genetic causes.³⁵ Dysfunction of inhibitory neurons containing nitric oxide and VIP innervating the LES and proximal portion of the stomach is postulated to be the major mechanism underlying the motor dysfunction of achalasia. Neural degeneration with resultant denervation of the smooth muscle segment of the esophagus has been demonstrated in patients with achalasia.³⁶ An autoimmune or inflammatory mechanism is suggested by the presence of T lymphocytes infiltrating degenerating nervous fibers.³⁷ Recent work demonstrates that the lymphocytes infiltrating the LES in achalasia patients are enriched for cytotoxic lymphocytes and that a larger than expected proportion of these lymphocytes target herpes simplex virus (HSV) antigens, suggesting that achalasia may be an autoimmune response to HSV-1 antigens.³⁸ Patients with achalasia exhibit exaggerated LES contractions in response to acetylcholine and cholecystokinin (CCK), a classic deinnervation response, suggesting that lack of inhibitory neurons is the primary defect.³⁹ Loss of regulatory inhibition of the sphincter tone results in failure of the LES to relax. Failure of the LES to relax and high resting LES pressure create a functional esophageal obstruction. Over time, this obstruction results in failure of the muscles of the esophageal body with esophageal dilation and aperistalsis. Muscle from the LES in patients with achalasia does not relax compared to muscle from normal individuals.⁴⁰

Restoration of normal motility in the damaged esophagus is not possible and normal peristalsis and LES relaxation are not achievable with any therapeutic modality. All treatment options are targeted at reducing pressure across the LES, which will facilitate esophageal transit by gravity. Reduction of pressure across the LES can be achieved by surgical myotomy, pneumatic dilation, or pharmacologic agents; the choice of treatment depends on the patient’s comorbid medical conditions. Because surgical myotomy is the most effective method to provide long-term pressure reduction across the LES, this treatment modality should be offered to patients who are good surgical candidates.⁴¹ Anterior esophageal myotomy is carried out across the esophageal sphincter and should be extended a few centimeters along the anterior gastric wall. Because myotomy destroys the LES in the setting of hypomotility of the esophageal body, inadequate esophageal acid clearance is a potential source of uncontrolled gastroesophageal reflux. Whether an antireflux procedure should be combined with esophageal myotomy remains controversial.⁴² Myotomy and fundoplication (Dor, Toupet, or loose Nissen techniques) is usually done laparoscopically through the abdomen. Residual gastroesophageal reflux has been reported in 10% to 40% of patients treated in this way and overall results are satisfactory in 80% to 100% of the patients.

The most effective nonsurgical treatment of achalasia is pneumatic dilation. The goal of this treatment is to “rupture” the LES. This result is obtained with inflation of a balloon across the LES tearing the muscle fibers of the sphincter. The balloons have different sizes (3.0, 3.5, and 4.0 cm), and clinical response is directly proportional to the size of the balloon used for dilation. The procedure can be done on an outpatient basis with minimum discomfort to the patient. With pneumatic dilation, 1-year treatment success rates of greater than 80% are reported, but by 10 years the rate of dysphagia control falls to 61%. Up to 64% of patients require multiple dilations to achieve long-term symptom control.⁴¹ Esophageal perforation is the main complication, with an incidence of about 2%.

Muscle relaxants such as calcium channel blockers or sublingual isosorbide dinitrate can be used before meals or to relieve symptoms. The efficacy of these medications is variable

ALGORITHM 64.1. A proposed approach to the patient with achalasia. Pt, patient; F/U, follow-up. (Adapted from Richter JE. Oesophageal motility disorders. *Lancet* 2001;358:823–828.)

and usually decreases with prolonged use.⁴³ Injection of botulinum toxin into the LES is a relatively new nonsurgical approach for the treatment of achalasia. Botulinum toxin inhibits the release of acetylcholine from nerve terminals, counteracting the effect of loss of the inhibitory neurotransmitters. This treatment has an initial reported efficacy rate of about 80% to 85%. Unfortunately, symptom recurrence occurs in more than 50% of patients within 6 months.⁴⁴ Receptor regeneration has been postulated as the main cause of failure after botulinum toxin injection. Some authors reported that myotomy can be more difficult and less effective after botulinum toxin injection.⁴⁵ Patient selection is extremely important when considering this type of treatment for achalasia (Algorithm 64.1). Patients with vigorous achalasia and older patients have been reported to have a prolonged response.

Improvement of symptoms is clinically used to evaluate the efficacy of pneumatic dilation or surgical myotomy. Symptom scores are not necessarily correlated with improvement in esophageal emptying; one third of patients have poor esophageal emptying despite symptomatic improvement.⁴⁶ Long-term patient follow-up has shown that good esophageal emptying is associated with better long-term results. Manometric or radiologic studies may help to define objective improvement in esophageal body motility and transit through the manipulated LES.

- 3 **Diffuse Esophageal Spasm.** Normal esophageal peristalsis interrupted by simultaneous contractions is the hallmark of diffuse esophageal spasm. Roughly 3% to 5% of patients assessed for esophageal motility disorders have diffuse esophageal spasm. Diffuse esophageal spasm can affect patients at any age but is more common in those older than 50 years. The typical symptoms of diffuse esophageal spasm are chest pain and dysphagia. The chest pain of diffuse esophageal spasm is similar to cardiac angina and may respond to nitrites; however, this symptom is usually not related to exertion and is often associated with meals. Intermittent, nonprogressive dysphagia to liquids and solids that can be precipitated by rapid eating, extreme food temperatures, heartburn, and stress is also commonly noted with diffuse esophageal spasm. An association of diffuse esophageal spasm with IBS, urinary disturbances, and sexual dysfunction has been reported.⁴⁷ Manometry is the diagnostic test of choice for the diagnosis of diffuse esophageal spasm. The manometric findings are consistent, intermittent simultaneous

contractions mixed with normal peristalsis and the presence of simultaneous contractions after 20% or more of wet swallows.⁴⁷ Newer work using combined manometry and intraluminal impedance monitoring (MII) shows that patients with diffuse esophageal spasm appear to segregate into two groups, those with effective peristalsis and those without effective peristalsis. Although there are limited data, using MII may play a role in selecting patients with diffuse esophageal spasm who may respond to surgical therapy.⁴⁸

The pathophysiology of diffuse esophageal spasm is unclear, but neural dysfunction has been suggested. Patients with diffuse esophageal spasm are more sensitive to hormonal and cholinergic stimulations, which cause esophageal contractions. Defects in inhibitory neural circuits have been implicated with a possible decrease in nitric oxide synthesis.⁴⁹ Gastroesophageal reflux and stress can produce diffuse esophageal spasm, and some patients with diffuse esophageal spasm develop achalasia, suggesting that dysfunction of inhibitory motor circuits may be a common pathogenetic mechanism to both disorders.

Diffuse esophageal spasm is a nonprogressive disorder, and treatment is predominately directed at symptomatic control. Because there are many nonesophageal causes of chest pain, and the relationship between esophageal dysmotility and chest pain can be difficult to confirm, it is critical to exclude these problems before embarking on a course of therapy for dysmotility-induced chest pain. Unrecognized gastroesophageal reflux disease (GERD) can be an important cause of esophageal spasm, so initial therapy should consist of a trial of proton pump inhibitors. If empiric GERD therapy does not improve symptoms, direct treatment of the esophageal motor disorder should be undertaken.⁴⁸ Two pharmacologic approaches have been utilized, smooth muscle relaxants such as nitrates and calcium channel blockers, and chronic pain control with antidepressant medication. No randomized trials support the use of nitrates, although uncontrolled studies suggest they help with chest pain symptoms. Three small, randomized trials of calcium channel blockers have shown that despite significant manometric changes, calcium channel blockers were no more effective than placebo in reducing chest pain.⁵⁰ Both tricyclic antidepressants and trazodone have shown benefits in symptom relief without improvements in manometric findings in randomized controlled trials.⁵¹ Despite these disappointing results, long-term follow-up of pharmacologically treated

patients suggests that most patients improve with reassurance. For patients with refractory symptoms, nonrandomized case series suggest that thoracoscopic and/or laparoscopic esophageal myotomy can result in good long-term symptom control when performed by experienced esophageal surgeons.⁵²

Esophageal Hypermotility. High-pressure contractions in the esophageal body have been described as “nutcracker esophagus.” High resting pressure in the LES is labeled as *hypertensive LES*. These entities have been grouped as a syndrome of spastic esophagus or esophageal hypermotility. Other causes of high-pressure contractions (e.g., gastroesophageal reflux) must be excluded prior to the diagnosis of esophageal hypermotility. The main symptom is chest pain, which is typically retrosternal and may radiate to the back. Dysphagia is an associated symptom in 50% of patients. Esophageal manometry is the most useful diagnostic test, with more than 40% of patients meeting manometric criteria. Manometry is characterized by mean distal esophageal peristaltic amplitude more than 180 mm Hg or mean distal duration greater than 6 seconds.⁵³ Treatment options are the same as those for diffuse esophageal spasm, although limited evidence suggests that surgery results in higher failure rates than in diffuse esophageal spasm. Response to treatment is not always predictable.

Esophageal Hypomotility. Low-amplitude peristaltic contractions, simultaneous contractions, or failed contractions in the distal esophagus have been grouped as hypocontracting esophagus or as ineffective esophageal motility. Peristaltic waves with amplitude of less than 30 mm Hg do not provide effective esophageal transport and clearance. Two major groups of patients with esophageal hypomotility exist, those with hypomotility secondary to systemic diseases and those with idiopathic hypomotility. Connective tissue disorders are the most common causes of ineffective esophageal motility, including scleroderma, rheumatoid arthritis, and systemic lupus erythematosus. Up to 80% of patients with scleroderma have esophageal motility disorders, likely secondary to diffuse vasculitis.⁵⁴ In the esophagus and gastroesophageal junction, vasculitis affects both smooth muscles and innervation, resulting in low-amplitude peristalsis of the distal esophagus and LES pressures below 10 mm Hg. Other causes of ineffective esophageal motility include autonomic neuropathy, amyloidosis, myxedema, multiple sclerosis, and alcoholism.

Gastroesophageal reflux is present in most patients with ineffective esophageal motility. Acid damage in the distal esophagus may contribute to dysmotility, and diminished esophageal acid clearance is responsible for increased acid exposure with ineffective esophageal motility.⁵⁵ The close relationship between esophageal hypomotility and GERD is emphasized by the fact that patients with esophageal hypomotility typically present with reflux symptoms rather than dysphagia.

Many patients with reflux disease have similar manometric findings to patients with primary or secondary esophageal hypomotility. Whether gastroesophageal reflux is the cause or the result of these abnormal manometric findings is a subject of debate. Some patients with esophageal hypomotility in the setting of GERD obtain marked improvement in esophageal contractility with antireflux surgery.⁵⁶ There is currently no specific treatment available to improve esophageal contractility, and symptomatic control of the gastroesophageal reflux is the only option for these patients.

Stomach

Diabetic Gastroparesis. Diabetic autonomic neuropathy is one of the major complications of diabetes mellitus and is most common in patients with long-term diabetes, poor

glycemic control, and peripheral neuropathy. Autonomic neuropathy may affect the entire gastrointestinal tract, producing constipation, abdominal pain, nausea, vomiting, dysphagia, diarrhea, and fecal incontinence. Diabetic gastroparesis may affect 50% of diabetic patients, although symptomatic gastroparesis is less common. Symptoms of diabetic gastroparesis include nausea, vomiting, and early satiety. In addition, impaired gastric motility predisposes to bezoar formation that can result in a vicious cycle of worsened gastric motility and early satiety. Delayed gastric emptying secondary to diabetic gastroparesis can make glucose homeostasis challenging, with resultant diabetic ketoacidosis or hypoglycemia. The diagnosis is usually suspected in a patient with symptoms of nausea, vomiting, and early satiety in the setting of diabetes. An upper endoscopy should be performed in all patients suspected of diabetic gastroparesis to exclude other organic causes of their symptoms. A nuclear medicine gastric emptying study is the “gold standard” diagnostic test for gastroparesis and can also be used in follow-up to assess response to treatment.

The pathophysiology of diabetic gastroparesis is complicated, incompletely understood, and multifactorial. Vagal nerve dysfunction can cause multiple changes in the normal physiology of gastric emptying. Vagal dysfunction can result in abnormal receptive relaxation of the stomach, decreased gastric antral contractility with failure of the antral pump, and prolonged contraction of the pylorus resulting in pylorospasm.⁵⁷ Neuropathy of the gastric enteric nervous system can exacerbate vagal dysfunction and may contribute to gastric myoelectric dysrhythmia.⁵⁸ Hyperglycemia itself can disrupt normal gastric motility and delay gastric emptying.⁵⁹

There is no single, specific treatment for diabetic gastroparesis. Aggressive glycemic control may prevent progressive neuropathy. Prokinetic agents such as metoclopramide and domperidone and dopamine antagonists promote gastric tone and improve gastric emptying. In addition, these drugs act as central nervous system–mediated antiemetic agents, reducing symptoms of nausea. The motilin agonist erythromycin has also been shown to be effective in patients with diabetic gastroparesis.⁶⁰ Erythromycin use has been limited by long-term tachyphylaxis. Pancreatic transplantation, by restoring glycemic control, has been reported to improve gastric motility as documented by gastric-emptying studies. Gastric electrical pacing using gastric pacemaker leads placed directly on the stomach has shown promise, but remains experimental.⁶¹

Postsurgical Gastroparesis. Postsurgical gastroparesis is a syndrome characterized by gastric hypomotility in the absence of mechanical obstruction. The incidence of this disorder has been estimated at 2% to 3% after partial gastrectomy and vagotomy.⁶² Postsurgical gastroparesis appears to occur more commonly after operations for gastric outlet obstruction and in diabetic patients. Patients with postsurgical gastroparesis develop symptoms of abdominal pain, postprandial nausea, vomiting, and weight loss months after gastric resection. The diagnosis is one of exclusion, and careful evaluation with endoscopy and barium studies is required to exclude mechanical gastric outlet obstruction. A solid-phase gastric emptying study is necessary and is the only abnormal test in 45% of patients with this motility disorder.⁶³

The pathogenic mechanism of this syndrome is related to loss of vagal innervation of the stomach, coupled with loss of antral pump function after antrectomy. Underlying gastric motor dysfunction in diabetic patients may also contribute to postsurgical gastroparesis. Treatment of postsurgical gastroparesis consists of prokinetic agents such as metoclopramide and erythromycin or revisional gastric surgery. Most authors recommend a 6- to 12-month trial of medical therapy prior to revisional surgery. Success rates of medical therapy have been disappointing, with response rates in the 20% to 30% range.⁶³ Surgical therapy is directed at eliminating the gastric reservoir

with a near-completion gastrectomy and Roux-en-Y gastrojejunostomy. In selected patient series, symptomatic success rates of 70% to 80% have been reported.⁶⁴

5 Dumping Syndrome. Dumping syndrome is a clinically defined spectrum of symptoms observed after gastric surgery thought to be a consequence of accelerated gastric emptying following vagotomy and bypass or destruction of the pylorus. Symptoms occur after the ingestion of food; they are absent in the fasting state. The incidence of dumping syndrome after gastric surgery is variable and depends on the operation performed. Overall, about 10% of patients will have clinically significant symptoms.⁶⁵ A diagnosis of dumping is made on clinical grounds and hinges on the presence of typical symptoms in a postoperative patient. Dumping occurs in the postprandial period and is classified into two forms. Early dumping occurs within 30 to 60 minutes of eating and typically presents with both gastrointestinal and vasomotor symptoms. Late dumping occurs 2 to 3 hours after eating and usually presents with only vasomotor symptoms. Gastrointestinal symptoms include postprandial fullness, crampy abdominal pain, nausea, vomiting, and explosive diarrhea. Vasomotor symptoms include diaphoresis, weakness, dizziness, flushing, palpitations, and an intense urge to lie down. In patients with severe dumping symptoms, weight loss and food fear may also be present.

Radioisotopic gastric emptying studies demonstrate rapid gastric emptying. Investigators have suggested a simple provocative test to confirm the diagnosis of dumping. After ingestion of 50 g of oral glucose, a heart rate rise of greater than 10 beats per minute in the first hour is a sensitive predictor of early dumping.⁶⁶ Late dumping is confirmed with this test by documenting typical vasomotor symptoms in the postchallenge period.

The pathophysiologies of early and late dumping are different. In early dumping, rapid delivery of hyperosmolar chyme into the small intestine secondary to rapid gastric emptying results in several maladaptive responses. The presence of hyperosmolar proximal small intestinal contents leads to fluid shifts into the intestinal lumen, causing intestinal distention and precipitating gastrointestinal symptoms. Rapid delivery of glucose to the proximal small bowel leads to both peripheral and splanchnic vasodilatation and blood pooling, which results in the vasomotor symptoms of early dumping. In addition, gastrointestinal hormone release is enhanced in patients with early dumping including secretion of enteroglucagon, VIP, peptide YY, pancreatic polypeptide, glucagonlike peptide 1 (GLP-1), and neurotensin.^{67,68} Rapid delivery of glucose to the small bowel followed by rapid glucose absorption causes late dumping symptoms by producing an exaggerated serum insulin release. Exaggerated insulin secretion, combined with rapid gastric emptying, results in an excess insulin state 2 to 3 hours after eating with subsequent hypoglycemia and vasomotor symptoms. The cause of the excess insulin secretion is unclear, but the enteric hormone GLP-1 may play a role in late dumping.⁶⁹

Most cases of dumping syndrome fade with time.⁷⁰ The initial mainstay therapy for dumping syndrome is dietary modification, which will effectively control dumping symptoms in most patients. An antidumping diet consists of (a) frequent small meals, ideally six or more per day; (b) a diet low in simple sugars with a moderate amount of fat and high in complicated carbohydrates, protein, and fiber; and (c) dry meals with liquid ingestion delayed at least 30 minutes after solid intake. Dietary fiber supplementation has been shown to help with late dumping. Acarbose, a competitive inhibitor of carbohydrate absorption, has also been shown to improve late dumping, although long-term use can cause malabsorption.⁶⁸ In patients with severe dumping, or those whose symptoms fail to respond to dietary modification, the next step should be the use of octreotide, the long-acting somatostatin analogue.

Octreotide acts to delay intestinal transit time, cause splanchnic vasoconstriction, and suppress the release of a variety of enteric hormones including insulin.⁶⁵ For patients with debilitating dumping symptoms that are refractory to dietary modification and octreotide, remedial surgery may be considered. A cautious approach is appropriate, as most cases of dumping will improve with time and no remedial operation has a 100% success rate. Reconstruction of the pylorus and conversion to Roux-en-Y gastrojejunostomy have both been used successfully to correct intractable dumping.⁷⁰

Gallbladder and Biliary Tract

Gallbladder Dyskinesia. The term *biliary dyskinesia* indicates a poorly characterized motility disorder of the gallbladder and the sphincter of Oddi. Gallbladder dyskinesia has been recognized as a cause of biliary symptoms, and may be a manifestation of generalized dysmotility of the gastrointestinal tract.⁷¹ The most common presenting symptom of gallbladder dyskinesia is abdominal pain in the absence of gallstones or other structural cause of right upper quadrant pain. The prevalence of biliary pain without gallstones has been estimated to be 6% to 21% with a 3:1 female-to-male predominance. The diagnosis of gallbladder dyskinesia is usually made by CCK cholescintigraphy obtained after an ultrasound negative for gallstones. During CCK cholescintigraphy, a gallbladder ejection fraction less than 35% is considered diagnostic of the disorder.

Defects in the function and distribution of CCK receptors on cells within the gallbladder wall with resultant abnormal responses to endogenous CCK have been implicated as causes of this disorder. In addition to an intrinsic motility disorder, inflammation and anatomic abnormalities have also been reported. Inflammatory bowel disease is associated with abnormal gallbladder contractility and patients with slow-transit constipation have been reported to have decreased gallbladder ejection fraction.^{72,73}

There is no effective medical therapy for this disorder. Laparoscopic cholecystectomy is the major treatment option for patients with gallbladder dyskinesia, with symptomatic improvement noted in 70% to 90% of selected patients. It is unclear if preoperative CCK cholescintigraphy results predict surgical results, although one study suggested that a gallbladder ejection fraction of less than 14% was associated with a higher likelihood of complete symptom relief.⁷⁴ Because of the frequent association of gallbladder dyskinesia with other motility disorders of the gastrointestinal tract, symptoms related to gastrointestinal dysmotility may not be relieved; nausea and vomiting are less likely to be relieved than postprandial abdominal pain. Although 81% of the patients with gallstones become asymptomatic after laparoscopic cholecystectomy, only 47% of patients with gallbladder dyskinesia are asymptomatic postoperatively.⁷⁵

Sphincter of Oddi Dysfunction. Sphincter of Oddi dysfunction describes a clinical syndrome arising from abnormalities of sphincter of Oddi contractility. The disorder can be caused by fibrosis and stenosis or by functional obstruction of the pancreaticobiliary junction. Ductal hypertension, hypersensitivity of the papilla, and possible ischemia from spastic contraction have been postulated as causes of pain, pancreatitis, and liver enzyme abnormalities.⁷⁶ The disorder can occur at any age and affects women more frequently than men. Although classically diagnosed in patients after cholecystectomy, this disorder can occur in patients with an intact biliary tree. Abdominal pain, usually in the epigastrium or right upper quadrant, is the most common symptom. The pain is often associated with oral intake and use of narcotics and does not respond to acid-reducing or prokinetic medical therapy. Jaundice and fever are uncommon. There are no characteristic findings on physical

TABLE 64.3 **DIAGNOSIS****ROME III CRITERIA FOR SPHINCTER OF ODDI DYSFUNCTION**

Epigastric or right upper quadrant pain and all of the following:
Pain last for ≥ 30 min
Recurrent symptoms occurring at different intervals
The pain builds up to a steady level
Pain requires medical attention and affects daily activities
No evidence of structural abnormalities
The pain is not relieved by bowel movements, postural change, or antacids
Supportive criteria
The pain may be associated with nausea and vomiting or back pain or awaken the patient from sleep
Adapted from Behar J, Corazziari E, Guelrud M, et al. Functional gallbladder and sphincter of Oddi dysfunction. <i>Gastroenterology</i> 2006;130:1498–1509.

examination aside from nonspecific abdominal tenderness. Because of the absence of a classic symptom or finding, patients with the diagnosis of sphincter of Oddi dysfunction are sometimes difficult to distinguish from patients with other organic or dysmotility disorders. Rome III criteria for the diagnosis of sphincter of Oddi dysfunction are listed in Table 64.3.⁷⁷

Initial diagnostic tests include complete blood count, liver function tests, and determination of serum amylase and lipase. Imaging studies should begin with ultrasonography to assess for stones and bile duct diameter. All of these tests are most sensitive when performed during active symptoms. Endoscopic retrograde pancreatography (ERCP) is conventionally used to exclude other pathologies that may cause symptoms similar to sphincter of Oddi dysfunction, although with the increased availability and accuracy of magnetic resonance cholangiopancreatography (MRCP), this test should be used before ERCP because it is noninvasive and carries a lower risk of complications. Sphincter of Oddi manometry is considered the “gold standard” for the diagnosis of sphincter of Oddi dysfunction and is the only method available to measure the activity of the sphincter directly. Manometry is usually performed during ERCP with selective cannulation of the pancreatic duct and biliary duct. Although a variety of noninvasive tests have been proposed to evaluate the possible diagnosis of sphincter of Oddi dysfunction, noninvasive testing cannot be recommended for general clinical use due to low sensitivity and specificity.⁷⁸ Invasive testing with ERCP and manometry has a high complication rate and is indicated only if definitive therapy is planned in the presence of abnormal results. Because of the difficulty in

TABLE 64.4 **CLASSIFICATION****MILWAUKEE CLASSIFICATION: SYMPTOMS**

■ BILIARY TYPE	■ DESCRIPTION
I	Patient with biliary-type pain; abnormal AST, ALT, or alkaline phosphatase (two times normal) on two or more occasions; and dilated CBD more than 8 mm diameter at US
II	Patient with biliary-type of pain but only one of two of the above criteria
III	Biliary-type pain only
AST, aspartate aminotransferase; ALT, alanine aminotransferase; US, right upper quadrant ultrasound; CBD, common bile duct. Adapted from Behar J, Corazziari E, Guelrud M, et al. Functional gallbladder and sphincter of Oddi dysfunction. <i>Gastroenterology</i> 2006;130:1498–1509.	

establishing the diagnosis of sphincter of Oddi dysfunction and predicting the response to therapy, the Milwaukee classification system was developed in an effort to correlate symptoms and diagnostic tests with abnormal manometric findings and predict the response to sphincterotomy (Tables 64.4 and 64.5). Abnormal liver tests in biliary type II disease may predict symptomatic response to endoscopic sphincterotomy.⁷⁹

The aim of therapy for sphincter of Oddi dysfunction is to decrease the resistance to the flow of bile and pancreatic juice. Medical therapy is based on the use of smooth muscle relaxants. Nifedipine has been shown to reduce pain in sphincter of Oddi dysfunction in 75% of the patients in the short term.⁸⁰ Long-term outcomes have not been reported. Despite the lack of long-term data, medical approaches should be considered when patients are not severely symptomatic (class II and III sphincter of Oddi dysfunction). Reduction of resistance at the sphincter of Oddi via endoscopic means by stenting or sphincterotomy is the mainstay of therapy for sphincter of Oddi dysfunction.⁸¹ According to the Milwaukee classification, manometry may predict the outcome from sphincter ablation in patients with biliary-type pain. The use of stents in sphincter of Oddi dysfunction is controversial, with a reported high incidence of pancreatitis (38%). Stenting may predict outcome from sphincterotomy when stenting provides resolution of pain for at least 12 weeks. Currently, endoscopic sphincteroplasty is standard therapy for sphincter of Oddi dysfunction, with clinical improvement reported in 55% to 95% of cases.⁸² The role of sphincter ablation is evolving; complication rates remain higher than in patients with ductal stones. Surgical

TABLE 64.5 **CLASSIFICATION****MILWAUKEE CLASSIFICATION: BILIARY SYMPTOMS AND RESPONSE TO TREATMENT**

■ PATIENT CHARACTERISTICS	■ ABNORMAL MANOMETRY (%)	■ SPHINCTEROTOMY EFFICACY IF MANOMETRY		■ INDICATION FOR MANOMETRY: PRIOR TO SPHINCTEROTOMY
		■ NORMAL (%)	■ ABNORMAL (%)	
Biliary I	75–95	90–95	90–95	Unnecessary
Biliary II	55–65	35	85	Highly recommended
Biliary III	25–60	<10	55–65	Mandatory

approaches such as transduodenal sphincteroplasty with pancreatic septoplasty have been largely replaced by endoscopic therapy. Patient selection is paramount considering the high complication rate for endoscopic therapy.⁸² Evolving manometric techniques are improving our understanding of sphincter of Oddi dysfunction. Patients with abnormal sphincter of Oddi manometry, without gastroparesis or a history of long-term narcotic use, appear to have the best response to endoscopic therapy.

Small Intestine

Chronic Intestinal Pseudo-obstruction. Chronic intestinal pseudo-obstruction is a clinical syndrome caused by ineffective intestinal propulsion and characterized by signs and symptoms of intestinal obstruction in the absence of mechanical cause.⁸³ The disorder is a rare clinical syndrome, caused by a variety of pathogenic mechanisms. Although sophisticated clinicopathologic classification systems exist for chronic intestinal pseudo-obstruction, important etiologies include visceral myopathies, visceral neuropathies, systemic disorders involving smooth muscle such as systemic sclerosis, developmental abnormalities of the myenteric plexus, and systemic neurodegenerative disorders.⁸⁴ Although small intestinal dysmotility is the prominent finding in most cases, the syndrome can involve all portions of the gastrointestinal tract from esophagus to colon.

Patients with intestinal pseudo-obstruction present with variable amounts of abdominal pain, distention, and vomiting. The vomitus often consists of partially digested food and can be feculent in character. Patients with small bowel involvement can develop bacterial overgrowth and may have symptoms of diarrhea and steatorrhea. In patients with significant colonic dysmotility, constipation symptoms may predominate. A family history of similar problems may be present in up to one third of cases, and many patients have a history of abdominal surgery.

On physical examination, patients may exhibit wasting with marked abdominal distention and visible bowel loops against the abdominal wall. Although tenderness is often present, peritonitis is unusual. In most ways it will be impossible to distinguish chronic intestinal pseudo-obstruction from true mechanical bowel obstruction, except for the chronic nature of symptoms and a history of prior episodes with waxing and waning severity. It is imperative for surgeons evaluating patients with chronic intestinal pseudo-obstruction to avoid mistaking this syndrome for mechanical bowel obstruction, because once a patient with chronic intestinal pseudo-obstruction has undergone abdominal surgery, the potential exists for both pseudo-obstruction and adhesive bowel obstruction to coexist. The best way to confirm a suspected diagnosis of chronic intestinal pseudo-obstruction is through barium contrast studies of the entire gastrointestinal tract. The identification of multiple sites of abnormality on such studies in the absence of a clear mechanical transition point is most consistent with the diagnosis. The finding of a single area of dilation isolated to the small intestine should raise suspicion of mechanical small bowel obstruction.

There is no definitive treatment for this motility disorder; no pharmacologic therapy or surgical procedure will correct the underlying motility disorder. Therapy is therefore directed at palliating symptoms and ensuring that patients receive adequate nutrition. A variety of promotility agents have been used. Metoclopramide and domperidone have not been found to be effective.⁸⁴ Erythromycin has shown benefit in some patients for up to 1 year, but tachyphylaxis appears to limit its long-term value.⁸⁵ Cisapride, although no longer available in the United States, improves symptoms in the majority of patients in noncontrolled trials.⁸⁶ Low-dose (50 µg) octreotide may be of benefit in patients with systemic sclerosis, but has not been shown to be useful in other patients with chronic intestinal pseudo-obstruction.⁸⁵

In patients with suspected pseudo-obstruction, avoiding operation is critical because a nontherapeutic operation for bowel obstruction will predispose the patient to adhesive mechanical bowel obstruction in the future. In patients with confirmed chronic intestinal pseudo-obstruction, surgical therapy can be important in palliating specific symptoms of the syndrome such as bloating and malnutrition, or in managing failures of medical management. For patients with localized dysfunctional bowel, bypass or segmental resection of the involved bowel can result in satisfactory long-term results.⁸⁷ In patients with diffuse intestinal involvement, venting enterostomy and intravenous access for long-term parenteral nutrition may represent the only surgical options. Small intestinal transplant has been reported in small series with good functional results.⁸⁸

Acquired Jejunoileal Diverticular Disease. Acquired jejunoileal diverticulosis appears to occur as a consequence of a small bowel motility disorder. This rare finding has a prevalence of between 0.1% and 2.3%, depending on whether autopsy or radiologic data are used.^{89,90} These lesions are usually found in patients in the seventh decade of life. There is no apparent sex predilection. These acquired lesions are pseudodiverticula whose wall includes only the mucosal and submucosal layers of the bowel. They are found on the mesenteric surface of the bowel and commonly lie within the mesentery. Eighty percent of patients have the diverticula localized to the jejunum; in 15% of patients, lesions are found in the ileum, and 5% have diverticula distributed throughout the small intestine. Eighty percent of patients, particularly those with jejunal diverticula, have multiple lesions.⁹¹

It has been postulated that these acquired lesions are caused by a motility disturbance of the involved intestine. Poorly coordinated neuromuscular function with ineffective peristalsis and resultant high intraluminal pressures cause protrusion of the mucosa through the muscular layers of the bowel wall at the point that the vasa recta enter the bowel wall. Abnormalities of both intestinal smooth muscle and the myenteric plexus found in patients with jejunoileal diverticulosis support this hypothesis.⁹² Mild variants of the same disorders may lead to the development of acquired small bowel diverticulosis. Pseudodiverticula are found in the colon and duodenum in 40% to 50% of patients with jejunoileal diverticulosis, supporting the role of a diffuse intestinal motility disorder in pathogenesis.

The role of surgical therapy in this motility disorder lies in the management of complications and in palliating symptoms secondary to the diverticula. The majority of patients (50% to 60%) have asymptomatic diverticula noted on radiologic study or found incidentally at laparotomy.⁹⁰ Because these patients are likely to remain symptom-free, there is no indication for resection in these instances. Twenty to forty percent of patients will present with a nonspecific constellation of chronic abdominal complaints including pain, postprandial bloating, diarrhea, malabsorption, and vitamin B₁₂ deficiency.⁹¹ In these patients, symptoms are related to bacterial overgrowth and malabsorption. Most of these patients respond to a regimen of a high-protein, low-residue diet coupled with vitamin B₁₂ supplementation and intermittent broad-spectrum antibiotic treatment. Only when this approach fails should resection be contemplated. Ten to fifteen percent of patients will present with acute complications, either bleeding, diverticulitis, or perforation, requiring urgent surgical intervention.⁹³ In emergent cases, resection of the involved segment of small bowel with anastomosis is the best surgical approach.

Colon

Colonic Inertia. Constipation is a common complaint, affecting up to 20% of the population.⁹⁴ Although the overwhelming majority of cases of constipation do not require

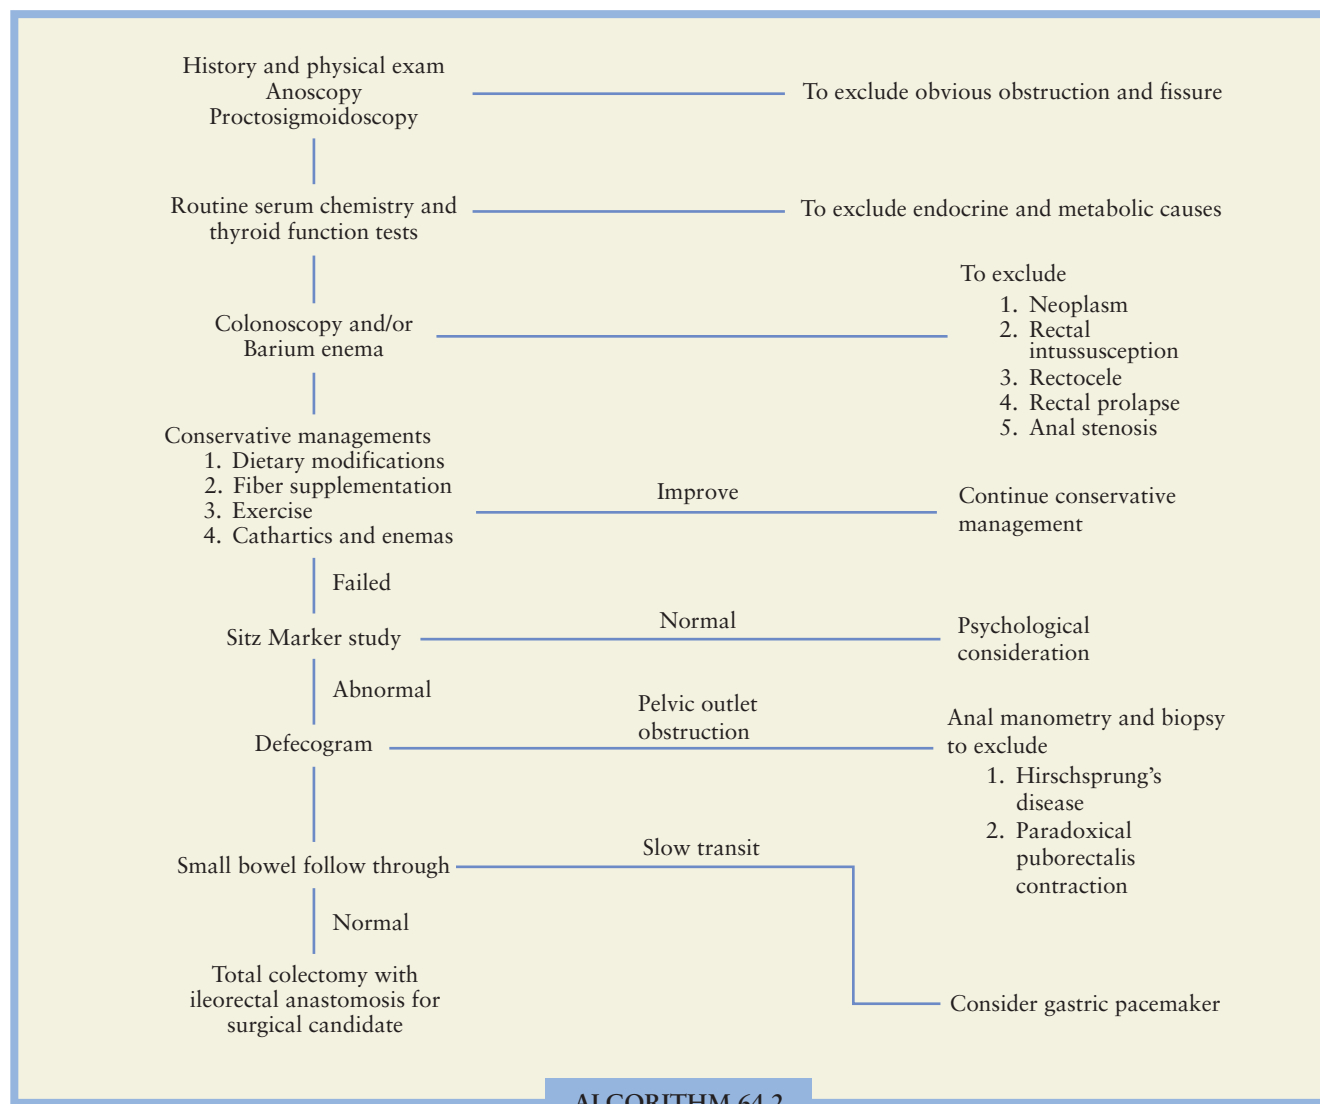

surgical attention, one disorder, idiopathic slow-transit constipation, is a motility disorder amenable to surgical therapy. Idiopathic slow-transit constipation or colonic inertia (CI) is caused by a variety of pathogenic mechanisms including abnormalities of myenteric plexus formation, disorders of extrinsic innervation of the colon, and disorders of colonic neuromuscular transmission. From a diagnostic and therapeutic standpoint, these disorders may be considered a single syndrome.⁹⁵

- 7 The diagnosis of colonic inertia is established in a chronically constipated patient with markedly prolonged colonic transit time in the absence of anorectal dysfunction. Patients typically present with complaints of needing regular assistance with bowel movement or of having one bowel movement every 7 days. The normal transit time through the colon can be assessed either with radiopaque markers or by scintigraphic studies. The radiopaque marker study involves the ingestion of a capsule containing 20 or 24 markers. Abdominal radiographs are then taken and analyzed after both 72 and 120 hours of ingestion. CI is defined as retention of at least 20% of the markers in the colon on the fifth day after ingestion. Pancolonic inertia becomes noted if the markers become diffusely scattered throughout the colon.⁹⁶ Scintigraphic colonic transit studies are less widely available, but require only 24 hours to obtain accurate segmental transit times.⁹⁷ Prior to the diagnosis of CI, tests

must be conducted to exclude causes originating from underlying endocrine and/or metabolic diseases. Colonoscopy should be performed to exclude the possibility of a neoplasm.

After establishing a diagnosis of slow colonic transit, anorectal function must be assessed, as disorders of anorectal function will slow colonic transit. Fluoroscopic defecography and anorectal manometry are used to exclude rectocele or rectal intussusception, which is often associated with obstructed defecation. A digital rectal exam can also be a valuable tool to aid a clinician in this diagnosis. Normal findings on these evaluations are required to establish a diagnosis of idiopathic slow-transit constipation.^{96,98}

The initial management of chronic constipation is medical, including behavior modification, dietary changes, fiber supplementation (25 g/d), and increased fluid intake to 1.5 to 2 liters daily. The use of psyllium and lactulose has been shown to improve symptoms.⁹⁹ Other oral agents, such as senna and milk of magnesia, do help, but the improvement is marginal and outcomes are not statistically significant.¹⁰⁰ The use of low-volume polyethylene glycol electrolyte solution administration does improve clinical outcomes.¹⁰¹ For some patients, biofeedback has helped with pelvic floor dyssynergia-type constipation.¹⁰² An overview of the management of chronic constipation is illustrated in Algorithm 64.2.

ALGORITHM 64.2

TABLE 64.6**SURGICAL OPTIONS FOR CHRONIC CONSTIPATION**

■ SURGICAL OPTION	■ COMMENTS
Total abdominal colectomy (TAC) with ileorectal (IR) anastomosis	Preferred procedure with over 90% success rate
Subtotal colectomy with ileosigmoid anastomosis	Predisposes to persistent constipation with over 50% conversion to TAC with IR anastomosis
Subtotal colectomy with cecorectal anastomosis	Preserves the ileocecal valve during surgery but can have complications of cecal dilation

In the few patients with intractable constipation found to have isolated colonic inertia, total abdominal colectomy with ileorectal anastomosis results in excellent functional outcomes in 90% of patients. Although subtotal colectomy with ileosigmoid anastomosis and subtotal colectomy with cecorectal anastomosis are available, the results are inferior and often require conversion to total colectomy with ileorectal anastomosis.⁹⁶ The key to good results with surgical therapy for constipation is careful preoperative evaluation of colonic function (Table 64.6). In series without complete evaluation, satisfactory outcomes occur in only 67% of patients.⁹⁸

Acute Colonic Pseudo-obstruction (Ogilvie Syndrome).

- 8 Acute colonic pseudo-obstruction is a clinical syndrome characterized by massive dilation of the colon in the absence of mechanical obstruction. The disorder is characterized by the loss of effective colonic peristalsis and subsequent distention of the proximal colon. This syndrome generally develops in ill patients, hospitalized initially for other significant medical problems, and is also observed in surgical patients after a variety of nongastrointestinal operations.¹⁰³ If left untreated, massive colonic dilation can result in ischemia of the right colon and cecum with associated perforation. The overall mortality rate of acute colonic pseudo-obstruction is quite variable, ranging between 0% and 32%, and appears to depend on the underlying cause of the pseudo-obstruction.¹⁰⁴ With the development of ischemia and perforation, mortality rises to 30% to 50%.

The pathophysiology of acute colonic pseudo-obstruction remains unclear. A current hypothesis invokes an imbalance in neural input to the colon distal to the splenic flexure with an excess of sympathetic stimulation and a paucity of parasympathetic input, resulting in a spastic contraction of the distal colon and functional obstruction.¹⁰⁵ Multiple independent circumstantial lines of evidence support this hypothesis, including the finding of colonic dilation in only the right and transverse colon in the majority of cases, the observation that epidural anesthesia improves the condition in a majority of cases, and the effective use of parasympathomimetic agents to treat the syndrome. The role of inhibitory neurotransmitters such as nitric oxide in the pathogenesis of acute colonic pseudo-obstruction has been suggested *in vitro*, but not yet confirmed in human studies.

Acute colonic pseudo-obstruction should be suspected in a hospitalized patient who develops marked abdominal distention over a period of 1 to 2 days. Obstipation is seen in the majority of patients, but up to 40% of cases will present with diarrhea or passage of flatus. Abdominal discomfort is present in the majority of patients, and tenderness on physical examination raises the concern for bowel ischemia.¹⁰³

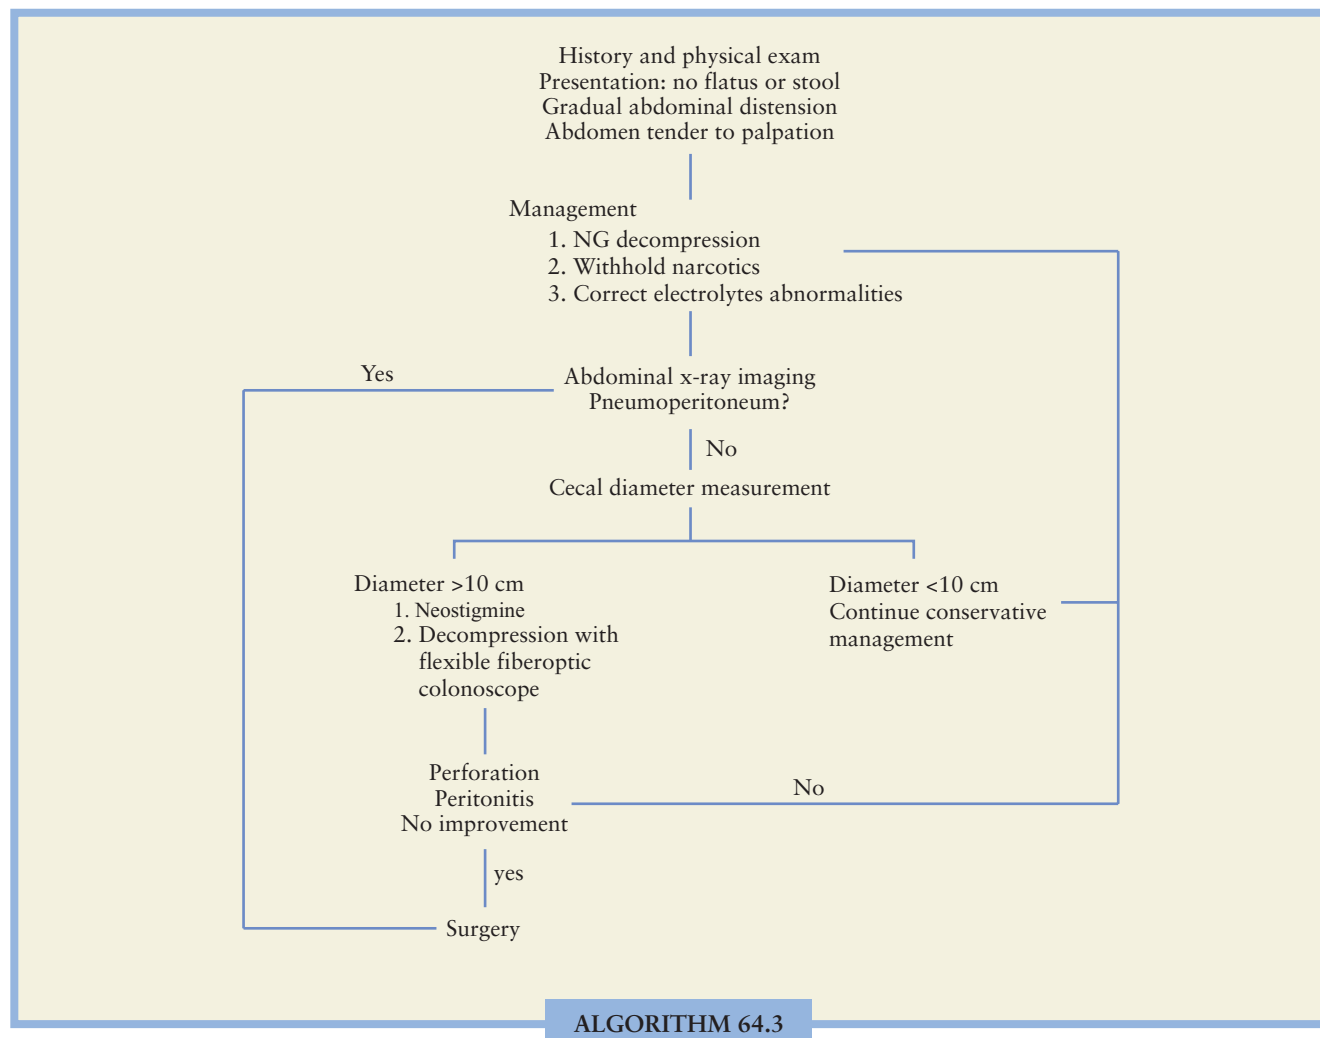

Plain films of the abdomen, with the finding of proximal dilation of the colon associated with a decompressed distal colon with some gas in the rectosigmoid region, are highly suggestive of acute colonic pseudo-obstruction. The diagnostic challenge initially is to exclude mechanical colonic obstruction,

and early performance of a water-soluble contrast enema is critical if mechanical obstruction cannot be ruled out on clinical grounds. The diameter of the cecum on plain film is important in directing the therapeutic approach to acute colonic pseudo-obstruction. Both animal studies and large retrospective human series suggest that the risk of cecal ischemia and perforation exists with cecal diameters greater than 12 cm and rises dramatically with cecal diameters greater than 14 cm.¹⁰³

For patients with a cecal diameter less than 10 cm, an initial trial of conservative therapy is indicated. Conservative therapy includes correction of electrolyte disorders, avoidance of narcotic and anticholinergic agents, hydration, mobilization, tap-water enemas, and placement of a nasogastric tube.¹⁰⁶ During this course of conservative therapy patients should receive frequent abdominal evaluation and serial abdominal radiographs to assess cecal diameter. Several small cases series suggest that resolution rates of acute colonic pseudo-obstruction approximating 90% can be achieved with a conservative regimen. Roughly 70% of the cases that resolve with conservative therapy do so within 2 days, suggesting that a 48-hour trial in stable patients is warranted.¹⁰⁷ However, postponing colon decompression beyond 4 days increases the mortality rate in patients with acute colonic pseudo-obstruction.¹⁰³

Patients who fail conservative therapy for more than 48 hours should be considered for active intervention with the first-line treatment consisting of intravenous administration of the cholinesterase inhibitor neostigmine. More than five non-controlled trials and one randomized controlled trial have shown that intravenous neostigmine at a dose of 2 to 2.5 mg given over 3 to 5 minutes results in immediate colonic decompression in 80% to 90% of patients, and sustained colon decompression is achieved in more than 60%.^{105,108} Because symptomatic bradycardia is a serious side effect of neostigmine, all patients being treated with the drug require cardiac monitoring. Neostigmine is contraindicated in patients with significant bradycardia. In patients with a contraindication to neostigmine and for those who fail to respond to the drug, decompressive colonoscopy is the next line of therapy. Colonoscopy to the cecum with evacuation of the contents of the proximal colon and placement of a long tube for decompression results in resolution of acute colonic pseudo-obstruction in 70% to 80% of cases. Roughly 40% of cases require multiple colonoscopies.¹⁰⁹

Colonoscopy in this setting is associated with a 2% to 3% perforation rate, and the case fatality rate of acute colonic pseudo-obstruction in patients requiring colonoscopy is up to 30%.¹¹⁰ In patients who develop findings suggestive of colonic ischemia or those who fail colonoscopic decompression, surgical therapy with either resection or a stoma is necessary, although it is associated with a 30% to 50% mortality rate.¹⁰³ Laparoscopic approaches have been reported for stoma creation and may avoid laparotomy in an elderly or frail patient. An algorithm for the management of Ogilvie syndrome is presented in Algorithm 64.3.

ALGORITHM 64.3. Treatment of Ogilvie syndrome. NG, nasogastric.

CHAPTER 65 ■ ACUTE GASTROINTESTINAL HEMORRHAGE

LAWRENCE T. KIM AND RICHARD H. TURNAGE

KEY POINTS

- 1 Eighty percent of patients with an acute gastrointestinal hemorrhage will be bleeding from the esophagus, stomach, or duodenum.
- 2 The most common cause of acute upper gastrointestinal hemorrhage is peptic ulcer disease, whereas the most common cause of lower gastrointestinal hemorrhage is a colonic diverticulum.
- 3 The use of nonsteroidal anti-inflammatory drugs, aspirin, and/or Coumadin is an important risk factor for acute gastrointestinal hemorrhage.
- 4 Approximately 80% of patients suffering an acute gastrointestinal hemorrhage will stop bleeding spontaneously; those who do not or those who rebleed are at particularly high risk to suffer an in-hospital complication, require operative control of their hemorrhage, or die.
- 5 Esophagoduodenoscopy (EGD) is an important early diagnostic test in patients suspected to have an acute upper gastrointestinal bleed.
- 6 Endoscopic therapy, such as thermal coagulation, is effective in controlling bleeding in as many as 90% of patients with bleeding gastric or duodenal ulcers.
- 7 The operative management of patients with bleeding peptic ulcers is used for those patients in whom endoscopic means are unsuccessful.
- 8 Endoscopic techniques (e.g., sclerotherapy or banding) will effectively stop acute variceal bleeding in as many as 90% of cases).
- 9 Localization of the site of bleeding is a crucial step in the successful operative management of patients with lower gastrointestinal hemorrhage.

1 Acute gastrointestinal (GI) hemorrhage is categorized as upper or lower depending on the location of the bleeding relative to the ligament of Treitz. Upper GI (UGI) hemorrhage (i.e., bleeding from the esophagus, stomach, or duodenum) accounts for about 80% of cases of acute GI blood loss, with most of the remainder coming from the colon. The small intestine is the site of hemorrhage in about 1% to 5% of cases.^{1,2} The incidence of UGI bleeding is estimated to be about 37 to 150 episodes per 100,000 individuals depending on the population sampled,^{3–5} whereas the incidence of lower GI (LGI) bleeding is about 20 cases per 100,000 individuals.⁶ Overall, GI hemorrhage accounts for roughly 300,000 hospitalizations and 30,000 deaths annually in the United States.⁷

The differential diagnosis of overt UGI and LGI hemorrhage and the relative frequency of the most common causes of GI

bleeding are shown in Tables 65.1 and 65.2 and Figure 65.1A, B, respectively. The most common causes of acute UGI hemorrhage are peptic ulcer disease (31% to 58%), gastritis and mucosal erosions (9% to 30%), and gastroesophageal varices (3% to 23%),^{1,3,8} whereas diverticulosis (24% to 47%), colitis (6% to 26%), neoplasms (9% to 17%), and angiodysplasia (2% to 12%) account for most instances of LGI hemorrhage.^{1,6,9–12}

PATIENT CHARACTERISTICS

Patients who suffer significant GI hemorrhage are more commonly older and male than are those individuals without GI bleeding. Furthermore, these individuals are more likely to use alcohol, tobacco, aspirin, nonsteroidal anti-inflammatory drugs

FIGURE 65.1. A: The relative frequency of the most common causes of upper gastrointestinal (UGI) hemorrhage in the United States. These data represent the percentage of patients with each of these causes of UGI hemorrhage for 482 patients in a survey of the members of the American College of Gastroenterology published by Peura et al. in 1997.¹ These data are very similar to that reported by Vreeburg in a multi-institutional study of 951 patients sustaining a UGI hemorrhage in the hospitals in and surrounding Amsterdam.³ **B:** The relative frequency of the most common causes of lower gastrointestinal hemorrhage. These data, reported by Lingenfelter and Ell,⁶ are the percentage of patients with each of these causes of lower GI hemorrhage in 912 patients collected in five studies from Europe, the Orient, and the United States.^{1,9-12}

TABLE 65.3**CHARACTERISTICS OF INDIVIDUALS AT AN INCREASED RISK OF DEVELOPING ACUTE GASTROINTESTINAL BLEEDING**

Increased age
 Male sex
 Unmarried (vs. married)
 Perceived fair or poor health status
 Cardiovascular disease
 Diabetes mellitus
 Renal disease
 Difficulty with activities of daily living
 Low level of physical activity
 Increased numbers of medications
 Oral anticoagulant use

From Kaplan RC, Heckbert SR, Koepsell TD, et al. Risk factors for hospitalized gastrointestinal bleeding among older persons. Cardiovascular Health Study Investigators. *J Am Geriatr Soc* 2001; 49(2):126–133.

ate-adjusted hazard ratio for subjects who smoked more than half a pack per day was 2.14 (95% confidence interval [CI] = 1.22, 3.75) for upper GI bleeding.¹³

Certain medications increase the risk of GI hemorrhage.

- 3 Many studies have related the use of NSAIDs and aspirin to significant GI bleeding. The risk is particularly elevated for UGI bleeding, but NSAIDs increase the risk of LGI hemorrhage as well. In Vreeburg's review of 951 patients with UGI hemorrhage, 41% used NSAIDs or aspirin.³ Van Leerdam reported that more than half of the patients bleeding from ulcers were actively taking NSAIDs or aminosalicic acid (ASA).¹⁷ Mellemkjaer et al. found that the observed to expected ratio of UGI hemorrhage in a cohort of 156,138 users of NSAIDs was 4.1 (95% CI = 3.8, 4.5).¹⁸ Other medications known to increase the risk of GI hemorrhage include spironolactone¹⁹ and the selective serotonin reuptake inhibitors (SSRIs).^{20,21}

The use of anticoagulants is also an important risk factor for acute GI bleeding. Coumadin is a particularly common cause. Kaplan et al. found that the age- and sex-adjusted hazard ratio for GI bleeding in patients taking oral anticoagulants was 2.59 (95% CI = 1.71, 3.93).¹³ Vreeburg et al. reported that 17% of their patients with UGI hemorrhage were taking Coumadin and the international normal ratio (INR) was greater than 4 in more than half of these patients.³ Because Coumadin metabolism can be affected by so many interfering substances, inadvertent Coumadin toxicity is a common problem, often presenting with GI hemorrhage. The use of antiplatelet agents such as clopidogrel and ticlopidine can also lead to GI hemorrhage.

CLINICAL PRESENTATION

Usually patients with overt GI bleeding present to the hospital after observing the passage of blood from the GI tract as hematemesis, melena, or hematochezia. Hematemesis is the vomiting of blood. Melena is a black, tarry stool resulting from the degradation of blood by enteric bacteria. It may occur with the loss of as little as 50 to 200 mL of blood.^{22,23} Bleeding from the small intestine or right colon may also appear black if it has remained in the GI tract for more than 12 to 14 hours.²⁴ Hematochezia is the passage of bright red blood from the rectum and is usually indicative of a lower GI source, although massive UGI hemorrhage may also cause hematochezia. Patients with acute GI bleeding may present with the hemodynamic consequences of hemorrhage

(NSAIDs), and anticoagulants.^{1,13} Predictors of risk for acute GI bleeding are shown in Table 65.3. Both upper and lower GI hemorrhage are more common in elderly than in younger individuals, with the average age being approximately 60 to 70 years.^{1,3}

Coexisting chronic illnesses are common in patients suffering either an upper or lower GI hemorrhage. Various studies have suggested a correlation between GI bleeding and correlates of poor health such as the use of multiple medications, reduced levels of physical activity, and inability to complete basic self-care tasks.^{13,14} Cardiovascular disease,¹³ hepatic disease, and renal disease¹⁵ are particular risk factors for acute GI bleeding. The presence of these chronic illnesses, as well as chronic obstructive pulmonary disease and cirrhosis, also greatly increases the risk of rebleeding after endoscopic control.¹⁶ Tobacco is also associated with higher rates of significant GI hemorrhage. A prospective cohort study of 5,888 men and women found that the multivari-

including light-headedness, dizziness, orthostatic syncope or near syncope, shortness of breath, and palpitations from tachycardia.

The medical history and physical examination provide important clues of the etiology of the patient's hemorrhage and the potential risk to the patient's life. The occurrence of melena after several days of worsening epigastric or upper abdominal pain suggests peptic ulcer disease, whereas hematemesis or melena following vomiting or retching strongly suggests a Mallory-Weiss tear. Massive, painless upper GI hemorrhage in a patient with cirrhosis suggests bleeding from gastroesophageal varices, although other etiologies including peptic ulcer disease or a Mallory-Weiss tear must also be considered. The medical history should elicit the presence of risk factors for GI hemorrhage alluded to in the previous paragraphs and listed in Table 65.3.

A systematic physical examination will document the magnitude of bleeding and the patient's ability to compensate for the blood loss. Massive hemorrhage is associated with signs and symptoms of hypovolemic shock, including cool, clammy, mottled skin, tachycardia, tachypnea, flat jugular veins, oliguria, and perhaps hypotension. These responses may be altered by advanced age, concomitant medical problems, and particular medications. Physical examination should also document evidence of cirrhosis and portal hypertension (i.e., ascites, spider angiomas, hepatosplenomegaly, palmar erythema, and large hemorrhoidal veins). A rectal examination may demonstrate bright red blood or melena.

PROGNOSTIC FACTORS

- 4 Most patients (about 80%) suffering GI hemorrhage will stop bleeding spontaneously; those who don't, or those who rebleed, are at particularly high risk to suffer an in-hospital complication, require operative control of their hemorrhage, or die. Sev-

eral classification systems have been developed to separate low-risk from high-risk patients with acute upper and lower GI hemorrhage. These systems have also been used to stratify those patients who may be safely managed as outpatients from those requiring in-hospital care.²⁵ The BLEED classification system addresses both upper and lower GI hemorrhage and consists of the following parameters: ongoing bleeding, low systolic blood pressure, elevated prothrombin time, erratic mental status, and unstable comorbid disease. Patients with at least one BLEED criterion are more likely to suffer in-hospital complications from UGI bleeding (31% vs. 4%) or lower GI bleeding (38% vs. 12%) than are patients who lack these criteria.²⁶

Prognostic systems for UGI hemorrhage have been more widely adopted than those for LGI hemorrhage. One widely used system is the Rockall score for assessing the risk of death and rebleeding in patients with UGI hemorrhage (Table 65.4). Using this model, Rockall et al. found that rebleeding occurred in less than 5% of patients and mortality was very low (0% to 0.2%) in patients with scores of 0 to 2. In contrast, one fourth to nearly one half of patients with a Rockall score of 5 to 8+ rebled; the mortality rates for these patients were 11% to 41%. In this study, rebleeding significantly affected the likelihood of death, particularly for patients with intermediate scores of 3 or 4 and 5 to 7 in which there was a three- to fivefold increase in mortality rates.²⁷

The Rockall classification has been widely accepted as accurate and, importantly, has been externally validated.^{28–31} However, the full classification scheme requires endoscopic assessment. An alternative scoring system based on clear and readily available clinical indices has been proposed, called the Glasgow-Blatchford bleeding score (GBS, Table 65.5). This scoring system has been subjected to a multi-institutional trial and found to be more accurate than the Rockall system.³² These authors suggested that patients with a score of 0 can be safely managed as outpatients.

TABLE 65.4

ROCKALL RISK SCORING SYSTEM AND RATES OF REBLEEDING AND MORTALITY

■ SCORE									
Variable	0		1		2		3		
Age	<60 y		60–79 y		≥80 y

^bKnown history, or clinical and echocardiographic evidence, of cardiac failure.

Adapted from Stanley AJ, Ashley D, Dalton HR, et al. Outpatient management of patients with low-risk upper-gastrointestinal haemorrhage: multicentre validation and prospective evaluation. *Lancet* 2009;373(9657):42–47.

INITIAL EVALUATION AND RESUSCITATION

Upon presentation, patients with GI bleeding should have placement of two large-bore intravenous lines in peripheral veins and intravascular volume resuscitation begun with an isotonic saline solution. Most patients stop bleeding spontaneously, and crystalloid volume resuscitation is all that is required. Blood should be drawn for type and cross match, complete blood count with platelet count, electrolyte determination, liver function tests, and coagulation profiles. It is important to emphasize that on presentation, the hematocrit or hemoglobin level may not accurately reflect the magnitude of acute blood loss. Estimates of the severity of hemorrhage must be based on clinical parameters.

The massively bleeding patient should receive packed red blood cells to restore intravascular volume and oxygen-carrying capacity. The decision to transfuse blood or blood products depends on the individual needs of the patient and the cause of the bleeding. The risks of the blood products (i.e., infection and allergic reactions) must be weighed against the risks of withholding transfusion (i.e., anemia, decreased oxygen-carrying capacity, coagulopathy). In general, blood products are used early in the management of patients with limited cardiac and pulmonary reserve who are unable to withstand or compensate for an acute reduction in their systemic oxygen delivery and those with lesions that are at particularly high risk for continued or recurrent hemorrhage (e.g., gastroesophageal varices).

Careful hemodynamic monitoring of these potentially critically ill patients is vital to successful management. Patients who are actively bleeding and those who have recently sustained significant hemorrhage should be admitted to an intensive care unit for close monitoring of hemodynamic parameters and evidence of continued or recurring hemorrhage. The presence of significant underlying illnesses, such as cardiac, renal, hepatic, or pulmonary insufficiency, may necessitate invasive cardiac monitoring with cardiac and arterial catheters. The information gained from these devices allows

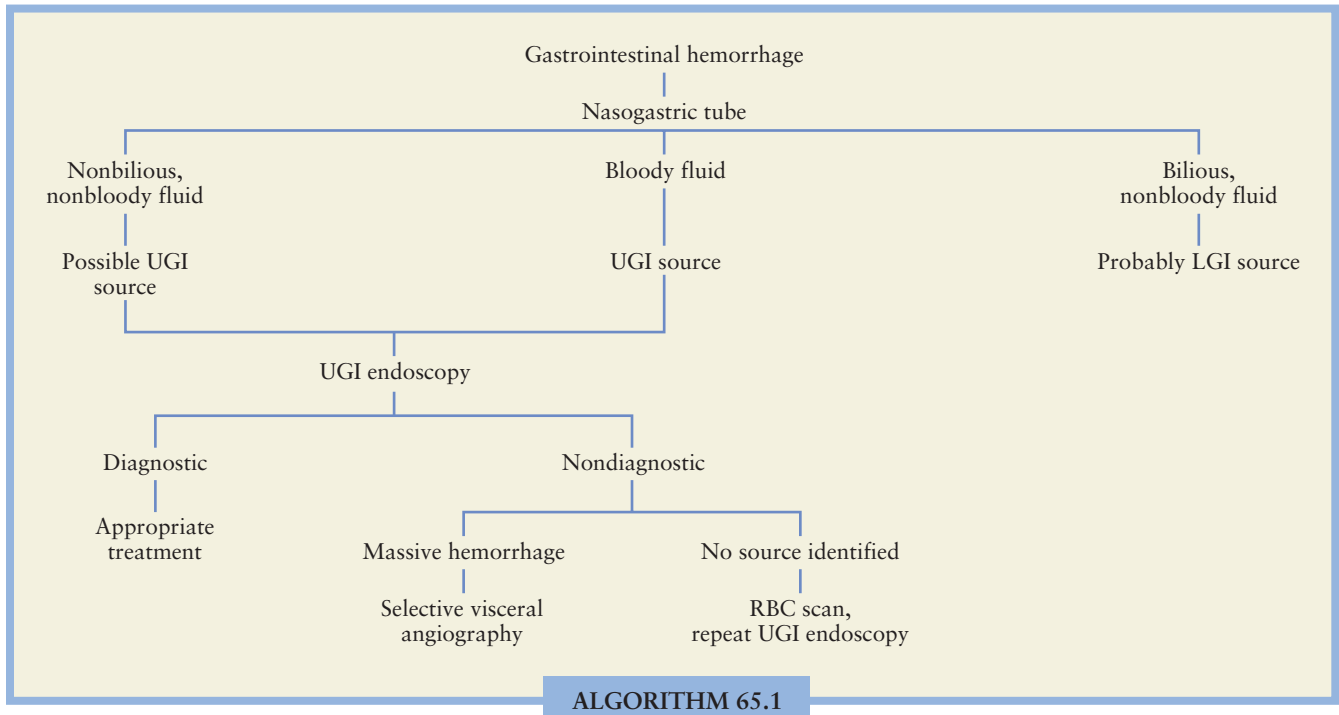

cardiac performance to be optimized during intravascular volume replacement. Central venous catheterization should be performed only after initial volume resuscitation through peripheral sites. The placement of a urinary catheter and frequent monitoring of heart rate, blood pressure, gastric aspirate, urine output, and mental status are the minimum necessary to monitor patients who have suffered GI hemorrhage. The importance of prompt, adequate resuscitation and diligent observation cannot be overemphasized as the cornerstone for managing these potentially mortally ill patients.

DIAGNOSTIC APPROACH

After the restoration of circulating blood volume, the next step is to identify the source of bleeding so definitive therapy may be instituted. If the patient presents with hematemesis, localization of the bleeding to the esophagus, stomach, or duodenum is relatively straightforward and esophagogastroduodenoscopy (EGD) should be performed promptly to identify the source of bleeding. When blood or coffee-ground guaiac-positive material is present in the gastric aspirate, EGD should be utilized to define the site of bleeding. Bright red blood per rectum strongly suggests a lower GI source of bleeding unless the patient is hemodynamically unstable, in which case the hemorrhage may originate from a source proximal to the ligament of Treitz. A generalized approach for evaluating patients with acute upper and lower GI hemorrhage is presented in Algorithm 65.1.

Gastric Aspiration

In the absence of hematemesis, aspiration of gastric fluid after the placement of a nasogastric tube has been used to distinguish between an upper and lower GI source of bleeding. Two studies with more than 700 patients found that the presence of blood in the gastric aspirate was a good indicator of a UGI source; however, its absence was unreliable in predicting the presence or absence of a UGI source.^{33,34} In one study of 220 patients with a UGI source of bleeding, the sensitivity, specificity, and accuracy

ALGORITHM 65.1. Diagnostic steps in the evaluation of gastrointestinal hemorrhage.

of the nasogastric aspirate were 42% (95% CI = 32, 51), 91% (95% CI = 83, 95), and 66% (95% CI = 59, 72), respectively.³⁴ Despite the potential for inaccuracy, all patients with acute GI hemorrhage should have a nasogastric tube placed as the initial diagnostic modality since it is inexpensive and safe. While a clear aspirate does not rule out an upper GI source of bleeding, aspiration of blood confirms it.

Endoscopy

Esophagogastroduodenoscopy. EGD will identify the site of bleeding in about 95% of cases of UGI bleeding and is the initial diagnostic study for patients suspected of bleeding from the esophagus, stomach, or duodenum.^{35,36} The sensitivity of the procedure is significantly enhanced when performed within the first 24 hours of presentation.³ A systematic review of the literature found that early endoscopy (i.e., performed within 24 hours of admission) was associated with a decreased transfusion requirement and decreased length of stay.³⁷ A prospective randomized trial found that early endoscopy allowed the triaging of 46% of patients to outpatient care without any adverse effects.³⁸ Previous consensus guidelines and several cohort studies have related various endoscopic stigmata of recent or active hemorrhage to a heightened risk of rebleeding or continued bleeding.^{39–45} Laine and Peterson³⁹ analyzed data from 37 prospective trials in which patients with bleeding ulcers did not receive endoscopic therapy; they found that the rate of further bleeding was less than 5% for those patients with a clean ulcer base and increased to 10% for patients with a flat red spot, 22% for those with an adherent clot, 43% for those with a nonbleeding visible vessel, and 55% for those with active bleeding. Endoscopic features predictive of persistent or recurrent bleeding and mortality are shown in Tables 65.6 through 65.8. In addition to these ulcer-specific factors, endoscopy allows identification of lesions with a high risk of continued hemorrhage and mortality (i.e., gastroesophageal varices) and those with a low risk of continued bleeding, such as a Mallory-Weiss tear. The efficacy of endoscopy-based modalities to control UGI hemorrhage is discussed in subsequent sections.

Colonoscopy. Although the efficacy of colonoscopy in determining the cause of occult GI bleeding is undisputed, its role in the evaluation of patients with acute lower GI bleeding is less well agreed upon. The procedure is best suited for patients who are actively bleeding at the time of the study, but not massively bleeding. Colonic gavage with a polyethylene glycol solution will clear the lumen of clot and stool, providing adequate visualization of the mucosa. Others have reported good visualization of the mucosa even in the absence of mechanical bowel preparation.⁴⁶

A meta-analysis examined the role of colonoscopy as the primary diagnostic modality for patients with acute lower GI bleeding and found that 69% (range, 48% to 90%) of urgent colonoscopies identified a source or a presumptive source of bleeding.⁴⁷ Even in the setting of unprepped bowel, urgent colonoscopy has been shown to identify bleeding colon and distal ileal lesions in 82 of 85 patients (97%).⁴⁶ Stigmata of recent hemorrhage for lower GI bleeding are similar to those of UGI lesions and include an actively bleeding site, a nonbleeding visible vessel, and an adherent clot; these findings have been associated with continued hemorrhage and the need for urgent colectomy.^{9,48} Jensen et al. reported that 25% to 50% of patients with *any* of these three factors continued to bleed, or rebled, and required urgent colectomy.⁴⁹ Others have found colonoscopy to be less accurate in the diagnosis of lower GI bleeding. For example, Al Qahtani et al. reported a series of 136 patients in which colonoscopy identified only 45% of the sources of lower GI bleeding.⁵⁰

Enteroscopy. For those patients who present with hematochezia in whom the initial EGD and colonoscopy is nondiagnostic, repeating these studies before evaluating the small intestine is warranted given the very small frequency in which the bleeding originates from the small intestine (1%). Repeating the EGD and colonoscopy when the patient is better resuscitated will often detect lesions such as ulcers or vascular ectasias that were obscured by blood at the initial endoscopy or the vasoconstriction of the GI mucosa that accompanies hemorrhagic shock.

Endoscopy of the small bowel with an enteroscope or a pediatric colonoscope will allow inspection of the proximal 60 cm of

TABLE 65.6

PREDICTORS OF PERSISTENT OR RECURRENT BLEEDING IN PATIENTS WITH NONVARICEAL UPPER GASTROINTESTINAL HEMORRHAGE

	RANGE OF ODDS RATIOS FOR INCREASED RISK
Clinical Factors	
Age >65 y	1.3
Age >70 y	2.30
Shock (systolic blood pressure <100 mm Hg)	1.2–3.65
Health status (ASA class 1 vs. 2–5)	1.94–7.63
Comorbid illness	1.6–7.63
Erratic mental status	3.21 (95% CI: 1.53, 6.74)
Ongoing bleeding	3.14 (95% CI: 2.40–4.12)
Laboratory Factors	
Initial hemoglobin <10 g/dL or hematocrit <0.30	0.8–2.99
Coagulopathy (prolonged partial thromboplastin time)	1.96 (95% CI: 1.46, 2.64)
Presentation of Bleeding	
Melena	1.6 (95% CI: 1.1, 2.4)
Red blood on rectal examination	3.76 (95% CI: 2.26, 6.26)
Blood in gastric aspirate or stomach	1.1–11.5
Hematemesis	1.2–5.7
Endoscopic Factors	
Active bleeding on endoscopy	2.5–6.48
Endoscopic high-risk stigmata	1.91–4.81
Clot	1.72–1.9
Ulcer size ≥2 cm	2.29–3.54
Diagnosis of gastric or duodenal ulcer	2.7 (95% CI: 1.2, 4.9)
Ulcer location	
High on lesser curvature	2.79
Superior wall	13.9
Posterior wall	9.2

the jejunum⁵¹ and the use of a long video-enteroscope may allow visualization of 100 to 150 cm of intestine beyond the ligament of Treitz.⁵² Jensen et al., in an experience with more than 200 patients with obscure sources of GI bleeding, reported success in identifying the etiology in 79% of instances using enteroscopy.⁵³ In their experience, vascular ectasias and postbulbar ulcers were the most common causes of obscure GI bleeding.

Intraoperative enteroscopy using a combination of push enteroscopes per os and per rectum or via enterotomy can allow examination of the entire small bowel. While the endoscopist manipulates the scope, the surgeon manually advances the bowel over the endoscope. After the bowel is telescoped onto the endoscope, it is slowly withdrawn while the endoscopist examines the mucosal lumen and the surgeon watches the transilluminated bowel wall. While this technique can be effective, it is limited by its invasive nature.⁵⁴

Double-balloon Enteroscopy. This technique utilizes a long enteroscope and a long overtube. Both the overtube and the enteroscope have balloons at the end. When the balloon of the enteroscope is inflated, it “grabs” the mucosal surface and allows advancement of the overtube, whose balloon is deflated. The overtube balloon is then inflated while the enteroscope

balloon is deflated. The enteroscope is then advanced while the inflated overtube balloon grips the mucosa. Using these alternate inflation–deflation cycles, long-distance advancement of the enteroscope has been achieved.² In one U.S. multicenter study, the average distance achieved was 360 cm with a diagnosis made in 43% of cases.⁵⁵ In some cases lesions may be seen that are missed by other techniques.⁵⁶

Wireless Capsule Endoscopy. Imaging of the small intestine is also now possible with a wireless capsule endoscope consisting of a battery, light source, imaging-capturing system, and transmitter. This capsule endoscope is 11 × 30 mm and is moved solely by peristalsis. This system captures and sends up to two images per second for about 8 hours to an ultra-high-frequency band radiotelemetry unit worn by the patient. The location of the capsule is suggested by the strength of the signal. Several studies have shown high diagnostic yields using this technique and found it to be superior to push enteroscopy in patients with obscure GI bleeding (reviewed in reference 2). One difficulty with this technique is the very large amount of data to be reviewed. For an 8-hour study, 57,600 images are generated. Even at high frame rates, manual review of the images is difficult and time consuming at best. Software is

available to limit the examiner's review time, but its accuracy is not currently known.

Selective Visceral Arteriography

Selective visceral arteriography is primarily useful in patients with upper or lower GI bleeding in whom endoscopy cannot be performed or has been unsuccessful in determining the site of ongoing rapid hemorrhage. Successful angiographic identification of the source of bleeding occurs in 27% to 86% of instances and depends primarily on the presence of active arterial bleeding at the time of the study^{50,57,58} (Fig. 65.2). The extravasation of contrast may be detected if the patient is bleeding at rates greater than 0.5 to 1 mL/min⁵⁹; this correlates

clinically with the requirement for continuous volume infusion to maintain hemodynamic stability. Pennoyer et al., however, were unable to identify any clinical parameter (including tachycardia, number of transfusions, or orthostatic hypotension) that could increase the diagnostic yield of selective angiography, including scintigraphy demonstrating ongoing

bleeding.⁶⁰ Several groups have used heparin, vasodilators, or thrombolytics to improve the diagnostic yield of arteriography in patients with nondiagnostic studies. Mernagh et al. found that the administration of heparin intravenously for 24 hours increased the diagnostic yield of visceral angiography from 33% (6 of 18) to 67% (12 of 18).⁶¹ Others have found that the intra-arterial infusion of a vasodilator, heparin, and/or urokinase (a thrombolytic) failed to identify the source of bleeding in five of seven patients.⁶² It should be noted that these provocative techniques are not commonly employed.

One major advantage of visceral arteriography is its therapeutic potential. Transcatheter embolization of bleeding vessels was first reported in the early 1970s.^{63,64} Modern instruments allow superselective catheterization of terminal vessels, leading to satisfactory embolization with less risk for ischemic complications. Further discussion of therapeutic use can be found later.

Abdominal Scintigraphy

Abdominal scintigraphy with ^{99m}technetium (Tc)-labeled red blood cells (RBCs) lacks the spatial resolution and diagnostic precision of angiography and endoscopy; however, it is of most value in detecting intermittently bleeding lesions or those with very low rates of hemorrhage, such as vascular malformations. Abdominal scintigraphy utilizing ^{99m}Tc-RBCs has been shown to detect bleeding rates as low as 0.04 to 0.1 mL/min.^{65,66} In a review of seven retrospective studies with nearly 400 patients, the median diagnostic accuracy of scintigraphy was 82% (range, 52% to 95%); in this review, ^{99m}Tc-RBCs were incorrect in 5% to 48% of instances (median 18%).⁵⁸ Suzman et al. summarized 20 retrospective studies containing 804 positive studies and reported a false-positive rate of 19%.⁶⁷ Precise localization of the site of bleeding may be complicated by the rapid distribution of isotope throughout the intestine by peristalsis or by accumulation in the right colon. More recent techniques of cine-scintigraphy may improve the diagnostic accuracy⁶⁸ (Fig 65.3). One area where radionuclide

scanning has a clear role is in the diagnosis of Meckel diverticulum. ⁹⁹Tc-pertechnate is secreted by ectopic gastric mucosa in Meckel diverticula.⁶⁹ This study should be considered early in the evaluation of young individuals with lower GI bleeding.

Computed Tomography Scanning

Computed tomography (CT) scanning has been used to detect GI bleeding using a variety of specialized techniques.^{70–73} Usually these techniques have been applied in cases of obscure bleeding where standard techniques such as endoscopy have failed. In general, however, these have not been sufficiently sensitive for the fine mucosal imaging necessary in evaluating GI hemorrhage. Research continues, however, using newer multidetector CT scanning combined with oral and intravenous contrast.^{74–77} In the future, this may become a more available and useful technique.

COMMON CAUSES OF GASTROINTESTINAL HEMORRHAGE AND TREATMENT

Upper Gastrointestinal Hemorrhage

Peptic Ulcer Disease. Peptic ulcer disease is the most common cause of acute upper GI hemorrhage, accounting for nearly 40% of cases in most series, although this proportion may be decreasing.⁷⁸ About 15% to 20% of patients with peptic ulcer disease experience bleeding during the course of their disease, and as many as 20% of these patients will have bleeding as the initial manifestation. Hemorrhage is the principal cause of death from peptic ulcer disease and has replaced intractable pain as the most frequent indication for surgery. Complications of peptic ulcer disease occur more commonly in older patients who often have medical problems that profoundly influence their risk of morbidity and mortality.

FIGURE 65.3. Cine-^{99m}Tc erythrocyte scintigraphy showing extravasation of isotope in the right colon. Only a small portion of the image set is shown. Arrows point to accumulation of isotope in the right colon. Bleeding was due to delayed hemorrhage following endoscopic polypectomy.

Duodenal ulcers occur slightly more frequently than gastric ulcers. Penetration of the ulcer through the posterior wall of the duodenal bulb is associated with erosion into the gastroduodenal artery or one of its branches, resulting in brisk hemorrhage. Patients may present with hematemesis of bright red blood and clots or with melena alone. Between 80% and 90% of patients stop bleeding spontaneously during the initial stages of therapy with volume resuscitation and gastric lavage.

In general, patients with gastric ulcers tend to be older and have coexisting medical problems that increase morbidity and mortality compared with duodenal ulcers. Bleeding may occur from any site in the stomach, although ulcers located at the incisura are most common. At this site, involvement of the branches of the left gastric artery may result in brisk, if not torrential, hemorrhage. The clinical presentation of patients bleeding from gastric ulcers is similar to that of duodenal ulcers, with hematemesis, melena, and hematochezia.

An important risk factor for the development of GI hemorrhage and gastroduodenal ulcer formation is the use of NSAIDs. NSAID use has been associated with a continuum of mucosal injury ranging from small acute mucosal hemorrhages to large chronic ulcers. It has been estimated that 10% to 15% of regular NSAID users have chronic gastric ulcers.⁷⁹ Symptoms correlate poorly with the degree of mucosal injury since as many as 20% of ulcers penetrating the muscularis are asymptomatic.⁸⁰ Case-control and cohort studies have suggested that NSAIDs are associated with a relative risk of GI hemorrhage and ulceration ranging from about 2 to 9.1.⁸¹ Ketorolac, in particular, has been associated with a high risk of GI bleeding (relative risk approaches 25).^{82,83} The risk of NSAID-associated complications is highest in patients with a history of upper GI bleeding, the elderly, or those patients taking oral anticoagulants⁸⁴ or corticosteroids. Patients with a prior history of peptic ulcer disease also appear to be at increased risk of NSAID-associated GI hemorrhage and tend to have a significantly worse outcome when compared to individuals not using NSAIDs.^{85,86}

The tremendous frequency with which NSAIDs are used by the elderly underscores the magnitude of this problem. Individuals with a history of NSAID-induced hemorrhage may benefit from the prostaglandin E₁ analogue, misoprostol, which has been shown to prevent NSAID-induced gastric erosions and ulcers.⁸⁷ Histamine (H₂)-receptor blockers (ranitidine and cimetidine) are effective in preventing NSAID-induced duodenal ulcers, but appear to have little effect on the occurrence of gastric lesions.^{80,88,89} Proton pump inhibitors (PPIs) have also been shown to be protective in patients on NSAIDs, with greater efficacy than H₂ blockers.⁹⁰ NSAIDs are also associated with lower GI bleeding, including lesions not generally considered related to NSAID use, such as diverticulosis.^{91–93} Selective cyclooxygenase-2 (COX-2) inhibitors have been marketed as being safer than nonselective NSAIDs, although some of these have now been withdrawn from the U.S. market for other safety concerns. It appears that these selective inhibitors cause fewer upper GI problems overall than traditional NSAIDs, the main benefit being fewer uncomplicated ulcers. But there is no decrease in complicated events, including clinically significant bleeding episodes.⁹⁴ Selective COX-2 inhibitors do not appear to result in an improvement in lower GI bleeding events.⁹⁵

Medical Treatment. Once bleeding from the upper GI tract is confirmed, treatment with a PPI should be initiated. Acute use of a PPI has been shown in several studies to decrease rebleeding.^{43,96–99} Although the Scottish Intercollegiate Guidelines Network (SIGN) recommended withholding PPI therapy until after endoscopy,^{100,101} in our opinion the balance of evidence would suggest no harm and perhaps a benefit from early PPI use. An 80-mg intravenous bolus of omeprazole or pantoprazole followed by an infusion at 8 mg/h produces the most reliable acid suppression.¹⁰² All patients should be tested for

Helicobacter pylori infection and treated if found. Treatment of the infection significantly reduces the recurrence of hemorrhage when compared to no treatment or chronic antisecretory treatment alone.^{103,104} Interestingly, *H. pylori* infection may be less common in patients with bleeding ulcers than in those with nonbleeding ulcers.¹⁰⁵

Endoscopic Treatment. The endoscopic appearance of a bleeding ulcer has important prognostic and therefore therapeutic implications, as alluded to in Tables 65.6 and 65.7. A modification of the system employed by Forrest et al.¹⁰⁶ is shown in Table 65.8. In this system category I findings are indicative of active bleeding, while category II findings provide evidence of recent hemorrhage. In general, only actively bleeding ulcers (i.e., Forrest category I lesions) are treated endoscopically.

A variety of endoscopic techniques are available to arrest hemorrhage from bleeding ulcers. The precise method of treatment is less important than the correct selection of patients and the experience of the endoscopist. Mechanical ligation of bleeding vessels can be achieved with endoscopic ligation (banding) or endoscopic clipping or Endoloop ligation.^{107–109} Heater probes and monopolar and bipolar electrocoagulation probes also can effectively control upper GI hemorrhage. Monopolar probes apply high-frequency electrical current to the tissue, resulting in localized heating to 100°C and sealing of the bleeding vessel by coagulation necrosis of the surrounding tissue and vessel wall. Multipolar electrocoagulation (BICAP) probes consist of three equally spaced pairs of bipolar microelectrodes. This orientation of electrodes allows coagulation of tissue from tangential approaches and eliminates some of the disadvantages of the monopolar probe, such as the unpredictable depth of thermal injury, adherence of tissue, and clot dislodgement. Direct thermal coagulation of a bleeding point can also be produced by applying a heater probe, consisting of an aluminum tip coated with Teflon. The tip is rapidly heated to 250°C by an inner coil. The tip can be irrigated with a water jet to prevent accumulation of debris and clot. Heat conducted from the probe produces tissue coagulation to a depth of 1 to 5 mm.

Injection of epinephrine to induce vasoconstriction has been used successfully to control acutely bleeding ulcers, particularly as an adjunct to electrocautery or mechanical hemostasis with clips. A meta-analysis of 15 studies concluded that injection alone was inferior to either clips alone or clips plus injection.¹¹⁰ This study showed no difference between clips and thermocoagulation.

The injection of sclerosants has been well described as a method of treating esophageal varices and has recently been popular for controlling nonvariceal bleeding. Sodium morrhuate and ethanolamine oleate are most commonly used to treat esophageal varices, whereas ethanol and polidocanol are most commonly used for nonvariceal sites. These agents act by thrombosing bleeding vessels and causing necrosis and subsequent fibrosis of surrounding tissue. Clinical experience with sclerosants has been similar to that obtained with electrocoagulation. In one large multicenter study of 332 actively bleeding patients or patients with stigmata of recent hemorrhage who underwent injection of 98% alcohol around the lesions, less than 1% continued to bleed, 6% rebled, and only 3% required emergency operative intervention.¹¹¹

A meta-analysis of 25 randomized trials of endoscopic therapy for bleeding ulcers concluded that endoscopic treatment methods have a beneficial effect on survival by reducing the rate of recurrent hemorrhage. This analysis suggested that endoscopic therapy results in a relative reduction of 69% in recurrent bleeding, 62% in emergent surgery, and 30% in mortality rate, with the greatest benefit seen in actively bleeding ulcers and ulcers with nonbleeding visible vessels.¹¹² The effectiveness of early aggressive endoscopic diagnosis and treatment is further supported by a report of 562 patients bleeding from a variety of causes, of whom only 2.5% required emergency operations to control hemorrhage.¹¹³

7 Operative Treatment. The successful use of endoscopic therapies has relegated operative procedures to a rescue role for those cases in which endoscopy is unsuccessful in arresting hemorrhage. Numerous studies have attempted to identify those patients at greatest risk of continued or recurrent bleeding. Of the many factors examined, those associated with the highest risk of rebleeding included patients in hypovolemic shock during the initial endoscopy, ulcers greater than 2 cm in diameter, and endoscopic stigmata of recent or ongoing hemorrhage (Forrest type I and II lesions).¹¹⁴ Many studies have demonstrated the ability of endoscopy to identify those patients at greatest risk of rebleeding. In one review, the presence of active bleeding was associated with a 90% to 100% chance of continued or recurrent hemorrhage. A nonbleeding visible vessel had a 40% to 50% chance, adherent clot 20% to 30%, oozing without visible vessel 10%, flat spot 5% to 10%, and clean-based ulcer 1% to 2%.¹¹⁵ Even in those patients who rebleed following initial endoscopic therapy, two thirds may be successfully retreated endoscopically, thus avoiding operative intervention.⁷⁹ Factors that must be considered in decisions regarding the timing of operative intervention include the magnitude of the initial (or recurrent) hemorrhage, the physiologic ability of the patient to withstand continued or recurrent hemorrhage, and the likelihood of recurrent or continued hemorrhage. It is generally accepted that elderly patients and those with significant concurrent medical problems should undergo operative intervention earlier during the course of the hemorrhage since these individuals will poorly tolerate continued bleeding, recurrent hypotension, and repeated transfusions.

The type of operation depends on the pathology encountered. For bleeding gastric ulcers, the operation of choice depends on the patient's condition and location of the ulcer. For favorably located ulcers, excision of the ulcer with closure of the gastrotomy will suffice. If the ulcer is unfavorably located, for example, near the gastroesophageal junction, simple undersewing of the bleeding ulcer may adequately control bleeding.¹¹⁶ If a gastric ulcer is left in situ, follow-up endoscopy is necessary 4 to 8 weeks later to either confirm healing or obtain tissue to rule out malignancy. Extensive gastric resections such as antrectomy or subtotal or total gastrectomy are generally not performed in these unstable patients.

For patients bleeding from duodenal ulcers, truncal vagotomy, pyloroplasty, and oversewing of the bleeding vessel is the most widely used operation. Direct ligation of the bleeding vessel through the duodenotomy should incorporate the gastroduodenal artery proximal and distal to the ulcer as well as the transverse pancreatic artery.

Angiographic Embolization. Relatively little has been written about the use of transcatheter embolization for peptic ulcer disease. In general, angiographic embolization is used after failure of endoscopic treatment in patients who cannot or will not undergo surgery. One recent large review (including nonulcer upper GI indications) showed a high technical success rate (i.e., localization of bleeding and deployment of the embolic agent) but a clinical success rate of only 51%.¹¹⁷ Significant ischemic complications can occur also. While this technique has utility in select patients, it should not be considered a routine treatment option for bleeding peptic ulcers.

Stress Gastritis

Although studies in the 1960s and 1970s demonstrated acute erosions of the gastric mucosa in as many as 60% to 100% of critically ill patients, the incidence has markedly decreased over the past four decades. Factors postulated to have been important in this phenomenon include (a) the widespread use of prophylactic gastric alkalization, (b) improvements in the ability to detect and treat sepsis, (c) improvements in the abil-

ity to monitor and correct hemodynamic instability, and (d) the ability to provide adequate nutritional support of critically ill patients.

In general, stress gastritis is characterized by the appearance of multiple superficial gastric ulcerations within 12 to 14 hours of an acute injury. These lesions, initially localized to the fundus and body of the stomach, later involve the entire gastric surface. Patients at greatest risk include those with sepsis, major burns, or severe trauma. Critically ill patients with a coagulopathy and respiratory insufficiency appear to be at highest risk of developing stress gastritis.^{118,119} In this setting, the disease appears to represent the gastric component of the multiorgan failure syndrome.
